plot observed by Al-Sader\textsuperscript{10} for the symmetrical azoalkanes leads us to the conclusion that in the gas phase, azo compounds fragment into two species in the rate-determining step. This is best represented by eq 2 for azoalkanes, and is consistent with a similar conclusion obtained in the study of 1-pyrazolines.\textsuperscript{18}

It is of particular interest to compare the activation energy obtained for 1, 2, and 4 with that of azoethane,\textsuperscript{19} 48.5 kcal mol\textsuperscript{-1}. The decrease in activation energy, 12.4–13.0 kcal mol\textsuperscript{-1}, may be attributed to the allylic resonance energy affecting the rate-determining step. This is comparable to the generally accepted value.\textsuperscript{20}

Since the full significance of the allylic resonance energy is manifested, the transition state is like the initial cleavage products.

Photochemical Redox Decomposition of Aqueous Azidopentaamminechromium(III)

Sir:

While photochemical substitution reactions of Cr(III) coordination compounds are quite common,\textsuperscript{1,2} photochemical redox decompositions of Cr(III) complexes have not been observed before.\textsuperscript{3} The results of the present investigation suggest that irradiation of aqueous Cr(NH\textsubscript{3})\textsubscript{5}N\textsubscript{3}\textsuperscript{2+} at pH 1 in the charge-transfer (ligand to metal) band leads to redox decomposion of quantum yields 0.45 at 313 mp and 0.4 at 263 mp, whereas irradiation at longer wavelengths in the ligand-field bands leads to photoaquation yielding Cr(NH\textsubscript{3})\textsubscript{4}(H\textsubscript{2}O)N\textsubscript{3}\textsuperscript{2+}.

Preliminary investigations as well as older observations\textsuperscript{4} indicate that the Cr–N bond in Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} is remarkably stable with regard to thermal substitution reactions. Contrary to other azidopentaamminechromium complexes, where, in thermal reactions preferentially the acido group is being substituted,\textsuperscript{5} Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} seems to show only ammonia aquation.

(3) For chromium oxalate complexes, some authors reported photo-redox decomposition; other investigators could not confirm these results. For a detailed discussion, see ref 1 and 2.

The photosensivity of Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} was first reported by Linhard and Berthold.\textsuperscript{4} Upon irradiation, they observed that the red color of an acidified solution of this complex turned to violet. This color change was accompanied by an increase of pH and formation of ammonium ions. Release of N\textsubscript{3}\textsuperscript{-} was negligible.

We could confirm these observations if the wavelength of irradiation was restricted to the region of the ligand-field bands (maxima and extinction coefficients of the first two ligand-field bands: L\textsubscript{1} 498 mp, ε 144; L\textsubscript{2} 382 mp, ε 93).\textsuperscript{5} The irradiated violet solution was treated with concentrated perchloric acid to precipitate an excess of the starting complex. The filtrate exhibited new absorption maxima at 515 and 393 mp. Since only ammonia was released, we conclude that Cr(NH\textsubscript{3})\textsubscript{4}(H\textsubscript{2}O)N\textsubscript{3}\textsuperscript{2+} was formed in the photo reaction. It could not yet be decided whether Cr(NH\textsubscript{3})\textsubscript{4}(H\textsubscript{2}O)N\textsubscript{3}\textsuperscript{2+} was formed as the trans or cis isomer.

Irradiation of Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} in 0.1 M HClO\textsubscript{4} at shorter wavelengths in the CTLM band (maximum at 263 mp with ε 5000) caused immediate evolution of nitrogen. Simultaneously, the red solution was bleaching and the pH was increasing. Ammonium was detected, but release of azide was negligible. Azide determinations were made by separation of N\textsubscript{3}\textsuperscript{-} by an ion-exchange technique and formation of an Fe\textsuperscript{3+}–N\textsubscript{3} complex which was determined spectrophotometrically at 460 mp, ε 3.68 X 10\textsuperscript{4}.\textsuperscript{6} After continued irradiation, the solution of Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} changed its color from red to a pale green. The photochemical reaction was followed spectrophotometrically. At all wavelengths, the optical density decreased except at the minimum at 435 mp where a slight increase was observed. Two clear isosbestic points at 410 and 442 mp excluded the formation of an intermediate species which could complicate the reaction by secondary photolysis. The decrease of the first ligand-field band at 498 mp was proportional to the absorbed light intensity at least up to a reaction amount of 40%. Hence the photochemical reaction follows a first-order kinetics. After photolysis to completion, the pale green solution had a new maximum at 423 mp with ε 64 per chromium.

Quantum yield determinations for disappearance of Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} were made by measuring the decrease of optical density at the maximum of the first ligand-field band at 498 mp, taking into account that the optical density at 498 mp drops to a few per cent when the solution is photolyzed to completion. K\textsubscript{2}Fe(C\textsubscript{2}O\textsubscript{4})\textsubscript{3} actinometry was used.\textsuperscript{7} At a 313-mp irradiating wavelength (Osram high-pressure mercury lamp, 100 W; Schott filter No. 313), the quantum yield was 0.45; at 263 mp (Hanovia xenon lamp, 150 W; Amino monochromator), the quantum yield was 0.4. The volume of evolved nitrogen was measured and compared with the decrease of optical density at 498 mp. Assuming that 1.5 mol of N\textsubscript{3}\textsuperscript{-} was formed per mole of chromium, about 90% of the required amount of nitrogen was recovered. These observations suggest that a redox decomposition occurs upon irradiation of Cr(NH\textsubscript{3})\textsubscript{4}N\textsubscript{3}\textsuperscript{2+} in the CTLM band according to

\[ \text{Cr(NH}_3)_4\text{N}_3^{2+} \rightarrow \text{Cr(NH}_3)_4^{2+} + \text{N}_3^- \]

The azide radical yields nitrogen. The other intermediate, Cr(NH₃)₅N₃²⁺, is very labile and decomposes to give Cr(II) and ammonia.

The fate of Cr(II) is not known because the photolyzed pale green solution has not yet been identified. However, we assume that Cr(II) is oxidized by air to binuclear complexes. Such reactions are typical for the oxidation of Cr(II) by air in acidic solution.

Strong support for the intermediate formation of Cr(II) is given by another experiment. If the redox photolysis of Cr(NH₃)₅Cl⁺₂ in a slightly acidic medium at 320 m meter is carried out in the presence of Co(NH₃)₅H₂O⁺, which is not photosensitive under these conditions, extensive formation of Co(II) does occur. Cr(II) is known to reduce Co(NH₃)₅H₂O⁺, which was first proposed for the photochemical redox reactions of Cr(III) complexes. The absence of azide aquation for Cr(NH₃)₅N₃⁺ upon irradiation in the CT band may be connected to the observation that Cr(NH₃)₅C₁⁺⁺ shows a large increase of halide aquation upon irradiation in the CT band. Both observations are consistent with a cage mechanism and the short lifetime of the azide radical. After homolytic splitting of the Cr₃⁺-N₃ bond, the azide radical may react fast enough to yield nitrogen before a charge recombination Cr⁺⁺→N₃ ↔Cr⁺⁺N₃⁻ can take place.

A Chiral Shift Reagent for Direct Determination of Enantiomeric Compositions

Sir:

We wish to report an nmr method for direct determination of enantiomeric compositions (optical purities) which we have applied successfully to several types of compounds including alcohols, ketones, esters, epoxides, and amines. This method involves use of a new chiral nmr shift reagent, tris[3-(trifluoromethylhydroxymethylene)-d-camphorato]europium(III) (1). Similar methods based on chemical-shift nonequivalence of enantiomers (in chiral solvents² or in the presence of a chiral shift reagent, tris[3-(3,3-dimethylhydroxyethylene)-d-camphorato]europium(III) (2)³) have been reported. However, these appear to be of limited applicability. Magnitudes of nonequivalence in chiral solvents are small (≤0.04 ppm)² which limits the usefulness of this technique for determining enantiomeric compositions. Large pseudocontact-shift differences for enantiomeric amines are observed with 2.³ However, with neutral compounds magnitudes of nonequivalence are generally too small to be useful. On the other hand, with 1 we have observed pseudocontact shift differences for enantiomeric alcohols of >0.5 ppm. Moreover, there is very little line broadening and in most cases we have achieved complete resolution of signals for enantiotopic⁴ protons with a 60-MHz instrument.

Compound 1 was prepared by reaction of 3-trifluoromethylhydroxymethylene-d-camphor (3) with europium(III) chloride in the presence of base.⁵ The chelate is an amorphous solid that softens at 100° and is very soluble in nonpolar solvents. The nmr spectrum of 1 ranges from +3 ppm to -1 ppm from TMS. Compound 3 was obtained by condensation⁶ of d-camphor with ethyl trifluoroacetate. Anal. Calcd for C₁₇H₃₁F₃O₃: C, 58.06; H, 6.09. Found: C, 58.17; H, 6.09.

Parts a and b of Figures 1 and 2 show spectra of carbon tetrachloride solutions of dl-2-phenyl-2-butanol (4) in 1:2.⁴

(1) Supported by the Research Committee of the Graduate School of the University of Wisconsin.
(5) K. J. Eisenbraut and R. E. Sievers, J. Amer. Chem. Soc., 87, 5254 (1965). The chelate was isolated by precipitation (as a resin) by addition of water and extraction into pentane. After extraction with water the dried pentane solution was concentrated to dryness and the residual 1 was dehydrated under vacuum. This material gave the same results as a sample purified by distillation (0.06 mm). Anal. Calcd for C₁₇H₁₆F₃O₃Eu: C, 48.38; H, 4.74. Found: C, 48.60; H, 4.72.
(7) Spectra were determined with a Varian A-60 spectrometer.

Figure 1. Spectra of 0.54 M 2-phenyl-2-butanol in CCl₄ in (a) the presence of 0.13 M tris(dipivalomethanato)europium(III) and (b) 0.42 M 1, and (c) spectrum of 0.3 M 1, 2-dimethyl-exo-2-norbornan in the presence of 0.42 M 1.
