ABSTRACT: The ability of silica to influence the mineralization of alkaline-earth carbonates is an outstanding example for the formation of biomimetic structures in the absence of any organic matter. Under suitable conditions, silica-stabilized carbonate nanocrystals can spontaneously self-assemble into hierarchical materials with complex morphologies, commonly referred to as “silica biomorphs”. However, growth of these crystal aggregates has largely been restricted to the higher homologues in the alkaline-earth series, i.e., SrCO3 and BaCO3, while corresponding architectures of the much more relevant calcium carbonate are quite difficult to realize. To systematically address this problem, we have crystallized metal carbonates in the presence of silica at high pH, using barium and strontium chloride solutions that contained increasing molar fractions of Ca2+. The resulting materials were analyzed with respect to their composition, structure, and crystallography. The obtained data demonstrate that the growth process is already strongly affected by small amounts of calcium. Indeed, morphologies typically observed for SrCO3 and BaCO3 remained absent above certain thresholds of added Ca2+. Instead, globular and hemispherical structures were generated, owing to fractal branching of carbonate crystals as a consequence of poisoning by silica. These alterations in the growth behavior are ascribed to relatively strong interactions of hard calcium ions with silicate species in solution, shifting their speciation toward higher oligomers and even inducing partial coagulation. This notion is confirmed by additional experiments at increased ionic strength. Our results further demonstrate that the observed hemispherical particles exhibit distinct polymorphism, with orthorhombic solid solutions (aragonite-type (Sr,Ca)CO3 and (Ba,Ca)CO3) being formed at lower Ca2+ contents, whereas Sr2+/Ba2+-substituted calcite prevails at higher Ca2+ fractions. In the case of Ba2+/Ca2+ mixtures, there is moreover an intermediate range where virtually identical morphologies were confirmed to be Ba2+-doped vaterite. These findings extend the variety of structures and compositions accessible in these simple systems, and may explain difficulties previously encountered in attempts to prepare CaCO3 biomorphs at standard conditions.

1. INTRODUCTION

In the past decades, the demand for new materials with specific properties has drastically increased. Modern synthetic approaches often follow strategies relying on bottom-up self-assembly of rather simple and cheap educts.1−4 In this context, so-called “silica biomorphs” have attracted growing attention, as these mesoscopically ordered architectures were generated, owing to fractal branching of carbonate crystals as a consequence of poisoning by silica. These alterations in the growth behavior are ascribed to relatively strong interactions of hard calcium ions with silicate species in solution, shifting their speciation toward higher oligomers and even inducing partial coagulation. This notion is confirmed by additional experiments at increased ionic strength. Our results further demonstrate that the observed hemispherical particles exhibit distinct polymorphism, with orthorhombic solid solutions (aragonite-type (Sr,Ca)CO3 and (Ba,Ca)CO3) being formed at lower Ca2+ contents, whereas Sr2+/Ba2+-substituted calcite prevails at higher Ca2+ fractions. In the case of Ba2+/Ca2+ mixtures, there is moreover an intermediate range where virtually identical morphologies were confirmed to be Ba2+-doped vaterite. These findings extend the variety of structures and compositions accessible in these simple systems, and may explain difficulties previously encountered in attempts to prepare CaCO3 biomorphs at standard conditions.

Recently, considerable progress has been made toward an understanding of the mechanisms leading to morphogenesis on the micrometer level, as well as the driving forces governing particle-based crystallization at the nanoscale.12,13,16,19,22 In essence, a scenario was proposed that segments the growth process into two principal stages: all characteristic architectures arise from a micrometer-sized carbonate crystal seed, which nucleates heterogeneously after some delay and soon adopts an elongated pseudohexagonal habit typical for orthorhombic carbonates.14,16,23 Upon further growth, this crystal starts to split at both ends along the c-axis due to nonspecific poisoning.
by oligomeric silicate species, leading to tilted outgrowths at noncrystallographic angles. Branching occurs mainly through the basal (001) faces and, after self-similar (fractal) propagation, yields increasingly bifurcated particles that develop through dumbbell-shaped forms eventually into closed spherulites or spacious cauliflower-like structures.\textsuperscript{6,13,14,16,20} From a morphological point of view, this growth behavior is similar to what has been observed for fluorapatite crystallization in gelatin matrices.\textsuperscript{24–26} In a subsequent second stage, fractal branching gives way to polycrystalline mineralization, where silica-sheathed carbonate nanoparticles are constantly nucleated and serve as building blocks for the construction of biomorphic aggregates, which then evolve free from symmetry constraints toward complex curved morphologies. The continuous production of nanocrystal units is explained by local variations of pH and supersaturation nearby the front of the aggregates, as a consequence of the inverse trends in solubility of silica and carbonate with pH in alkaline media: growth of carbonate particles causes a decrease of pH in their vicinity (due to bicarbonate dissociation), which leads to local precipitation of silica and stabilization of the crystallites.\textsuperscript{13,17} Ongoing silica condensation then re-increases the pH at the front, so that a novel event of carbonate nucleation is induced and the previous steps are reiterated. Thus, the mineralization of the two components is coupled via the local pH, resulting in alternating precipitation through autocatalytic processes.\textsuperscript{12,13,22} However, this dynamic interplay only occurs within a certain range of conditions, as determined by parameters like the bulk pH,\textsuperscript{14,27} and recent studies also demonstrated that the final morphologies displayed by silica biomorphs may strongly depend on subtle factors.\textsuperscript{15,16,19,21,28}

Another mandatory requirement for the formation of true silica biomorphs (i.e., nanocrystalline aggregates exhibiting sinuous shapes) seems to be the use of carbonates that crystallize in an orthorhombic structure, such as strontianite (SrCO\textsubscript{3}) and witherite (BaCO\textsubscript{3}; both being isotypic with the CaCO\textsubscript{3} polymorph aragonite). In fact, Ba\textsuperscript{2+} and Sr\textsuperscript{2+} salts can be mixed at arbitrary ratios without any change in the morphologies of the resulting biomorphs, which suggests that both metal ions are homogeneously distributed within the mature aggregates.\textsuperscript{9} Calcium carbonate—by far the most abundant mineral within the alkaline-earth series and of high relevance for industrial processes—also forms biomimetic structures in silica-rich environments.\textsuperscript{29–31} However, these precipitates usually consist of rhombohedral calcite (the stable modification at ambient conditions) and do not display intricate curved morphologies as those being characteristic for biomorphs (like worms or helicoids). Actual CaCO\textsubscript{3} biomorphs were in turn produced by tuning synthesis parameters in order to shift polymorph selection in the direction of aragonite. This was successfully accomplished by increasing the temperature to 80 °C, thus kinetically favoring the formation of aragonite,\textsuperscript{21} or by using suitable seed crystals.\textsuperscript{32} In this context, it is worth mentioning that calcium carbonate structures with comparable shape and complexity (e.g., spicules) have also been generated in the presence of polyelectrolytes like poly(acrylic acid) or poly(aspartic acid), where the (organic) polymers induce liquid-like mineral precursors that may yield nonequilibrium morphologies upon solidification.\textsuperscript{33} Clearly, it would be desirable to develop a bottom-up protocol allowing for the preparation of CaCO\textsubscript{3} biomorphs at room temperature, without the need for external triggers like seeds. Preliminary observations made in very recent work have indicated that silica-aragonite biomorphs might indeed grow spontaneously in silica gels under very particular conditions (i.e., specific concentrations, pH, location in the gel, etc.).\textsuperscript{34} However, detailed insight into the role of the different parameters and control over the final structures has not yet been gained.

Another potential way to generate CaCO\textsubscript{3} biomorphs at room temperature is to work with mixtures of calcium and barium or strontium, as it is known that both witherite and strontianite can incorporate Ca\textsuperscript{2+} into their crystal lattice (forming solid solutions).\textsuperscript{35,36} and that even minor amounts of the larger Ba\textsuperscript{2+} or Sr\textsuperscript{2+} ions can force calcium carbonate into the aragonite modification.\textsuperscript{38} Here, we have investigated the possibility of growing silica-aragonite biomorphs by crystallizing carbonates from mixtures of BaCl\textsubscript{2} or SrCl\textsubscript{2} and CaCl\textsubscript{2} under the influence of dissolved silica at high pH. To that end, we performed experiments in which the ratio of Ba\textsuperscript{2+}/Sr\textsuperscript{2+} to Ca\textsuperscript{2+} was systematically varied, at all constant metal ion concentration. The resulting precipitates were investigated in terms of morphology, composition and structure, focusing on the specific influence of the divalent calcium ions on morphogenesis.

2. EXPERIMENTAL SECTION

2.1. Materials. Barium chloride dihydrate (Sigma-Aldrich, ≥99%), strontium chloride hexahydrate (Sigma-Aldrich, ACS reagent, ≥99%), and calcium chloride dihydrate (Riedel-de Haën, ACS reagent, ≥99%) were used as received. The silica source was a commercially available water glass stock (Sigma-Aldrich, reagent grade, containing ca. 13.7 wt % NaOH and 12.5 wt % SiO\textsubscript{2}). All solutions and dilutions were prepared with water of Milli-Q quality and stored in tightly stoppered plastic bottles, to prevent silica contamination from glass walls and uncontrollable uptake of atmospheric CO\textsubscript{2}.

2.2. Crystallization Experiments. Growth of alkaline-earth carbonates in the presence of silica was carried out in stagnant solutions, following similar procedures as in previous studies.\textsuperscript{6,12,13,23,28} First, the silica stock was diluted with water by a factor of 1:350 (v/v) and then mixed at a ratio of 20:1 (v/v) with 0.1 M sodium hydroxide (Merck, p.a.). Crystallization was initiated by combining 5 mL of the different molar fractions of CaCl\textsubscript{2} (0, 0.02, 0.10, 0.20, 0.50, 0.80, and 1.00) next to either BaCl\textsubscript{2} or SrCl\textsubscript{2}. Experiments were conducted at 20 ± 1 °C in sterile 6-well microplates (Nunclon, polystyrene, 10 mL total volume, 9.6 cm\textsuperscript{2} bottom area, 1.7 cm in depth). Glass coverslips (22 × 22 mm) were placed as growth substrates on the bottom of the well before filling with growth solution (thus crystals were formed only on the top side of the substrate). After exposure of the samples to the atmosphere over predefined periods (varying between 18 h and 3 days and depending on the Ca\textsubscript{2+} content), the substrates were removed with a pair of tweezers and subsequently washed with water and ethanol (Baker, p.a.), followed by drying in air.

2.3. Characterization Methods. First, the time-dependent macroscopic behavior of the samples at distinct barium/strontium:calcium ratios was observed visually. To that end, time-lapsed series of photographs were recorded with a remote-controlled Canon EOS 350D digital camera. The pH of the samples was measured directly after combining reagents (i.e., the metal salt mixture with the silica sol) and after a period of 24 h by means of a polymer-based electrode (Mettler-Toledo, InLab Expert), which was connected to a Schott CG-843 laboratory pH meter. The initial pH was found to be 11.0 ± 0.1, independent of the CaCl\textsubscript{2} content and whether Ba\textsuperscript{2+} or Sr\textsuperscript{2+} was used, which is in good agreement with values reported for pure Ba\textsuperscript{2+} systems in previous work.\textsuperscript{12,23} Within 1 day, the pH decreased to 9.6 ± 0.1 in all samples due to in-diffusion of CO\textsubscript{2} into the alkaline solutions, forming carbonic acid which rapidly deprotonates to give carbonate and bicarbonate species.
Isolated precipitates were routinely studied by polarized optical microscopy using a Nikon Eclipse E400 transmission microscope, onto which a Canon EOS 350D camera was mounted for imaging. For scanning electron microscopy (SEM), aggregates were grown directly on a conducting foil, which was placed on the bottom of the wells as a growth substrate. After careful rinsing with water and ethanol, the foil carrying the precipitates was mounted directly on the SEM stub and coated with a thin gold layer. Specimens were investigated with a Zeiss LEO Gemini 1530 or a FEI Quanta 400 T microscope, at acceleration voltages ranging from 3 to 10 kV. Energy-dispersive X-ray (EDX) spectroscopy measurements were carried out at 10 kV with the help of an installed Oxford INCA microanalysis system. Spectra were recorded at three different positions on the stub, in order to average results for a given sample. X-ray diffraction (XRD) data were recorded on a STOE STADI P diffractometer using Cu Kα1 radiation and a germanium single-crystal monochromator (\(\lambda = 1.540598 \text{ Å}\)). Patterns were acquired over a 2θ range of 8°-90° at a scanning speed of 0.8°/min. Dynamic light scattering (DLS) experiments were performed with a CGS-3 goniometer system from ALV (Langen, Germany), which was equipped with an ALV-7004/FAST Multiple Tau digital correlator and a He–Ne laser operating at a wavelength of 638.2 nm. Equal volumes of 10 mM metal chloride solution (\(x_{\text{c}} = 0.02\)) and the silica sol were first passed through syringe filters (VWR, cellulose acetate, 200 nm) and subsequently combined in a vial. Next, 1.5 mL of the resulting mixture was transferred into a DLS cuvette, and measurements were started 20 s after mixing. The temporal evolution of particle size was traced over the following 30 min by performing consecutive runs of 60 s duration each. The average size of the scattering species was calculated by fitting monomodal equations to the experimental correlation functions.

3. RESULTS

3.1. Morphological Analysis. 3.1.1. Reference Experiments. First, reference experiments were performed in which witherite and strontianite were crystallized in the absence of Ca\(^{2+}\) under conditions commonly applied for the synthesis of silica biominerals (5 mM Ba\(^{2+}\) or Sr\(^{2+}\), 8.4 mM SiO\(_2\), pH \(\sim 11\)). The resulting aggregates exhibited morphologies very similar to those reported previously,\(^{6,8,11,14,15,23,54}\) without any significant morphological or structural differences between BaCO\(_3\) and SrCO\(_3\). Typical forms include regular helicoids, flat leaf-like sheets, as well as thicker and more tightly wound worms (Figure 1A–F).

Along with these complex polycrystalline structures, various fractal aggregates—globules, dumbbells, and clusters thereof—with diameters around 10 μm were frequently observed (Figure 2A), all of which arise from splitting of an initial rod-like carbonate seed crystal, as described above and explained in detail elsewhere.\(^{6,13,16}\) Bottom views reveal that bifurcation of the core crystal occurs along the [001] direction (Figure 2C), and that progressive branching first yields dumbbell-like particles (Figure 2A), which finally become closed to give spherulithic architectures (Figure 2B,D). These fractal structures are known to be precursors of the more characteristic noncrystallographic morphologies displayed by silica biominerals.\(^{6,13,16}\) After some time, laminar domains (composed of silica-stabilized nanocrystals) start to sprout radially from the globular units and subsequently grow flat in a nearly two-dimensional manner into extended sheet-like objects (Figure 1B,E, with the initial fractal clusters being visible in the center of the leaves). The more elaborate, curved ultrastructures (helicoids and worms, cf. Figure 1A,C,D,F) in turn emerge when sheets become curled at their rim and distinct segments begin to wind around one another; parameters determining the final shape of these twisted aggregates have been thoroughly discussed in the literature.\(^{13,22,23}\)

When crystallization was carried out under the same conditions but using 5 mM CaCl\(_2\) instead of BaCl\(_2\)/SrCl\(_2\), the solutions became turbid several minutes after mixing of reagents (see Figure S1 in the Supporting Information (SI)),

![Figure 1. FESEM (A–F, H, and I) and optical (G) micrographs of BaCO\(_3\) (upper panels), SrCO\(_3\) (middle panels), and CaCO\(_3\) (lower panels) structures formed upon precipitation from silica-containing solutions at high pH. (A–C) Silica-witherite biomorphs, showing helicoidal filaments (A), flat sheets (B), and worms (C) as main morphologies. (D–E) Silica-strontianite biomorphs, virtually indistinguishable from their BaCO\(_3\) counterparts. (G–I) Unusual calcite crystals, elongated along their c-axis and exhibiting dome-like outgrowths. Scale bars: (A,B) 50 μm, (C) 10 μm, (D) 20 μm, (E–H) 50 μm, and (I) 20 μm.](image-url)
in contrast to the previous experiments with Ba\(^{2+}\) and Sr\(^{2+}\). This can be ascribed to stronger interactions of the hard calcium ions with negatively charged silicate species existing in solution at high pH.\(^{39}\) Thereby, the divalent cations screen the charges and provoke polymerization of silica, causing coagulation and the deposition of a layer of silica gel on the bottom of the well. Within this layer, crystals with extraordinary shapes and fairly uniform dimensions (ca. 50 \(\mu m\)) grew within a period of about 3 days (Figure 1G–I), and were confirmed to be calcite by XRD (cf. Figure 6, below).

Closer examination suggests that these crystals are elongated along the crystallographic \(c\)-axis and consist of micrometer-sized, tabular subunits. Moreover, they display large dome-like outgrowths on one of their ends (Figure 1I). Similar morphologies and structures have been obtained previously by crystallization of CaCO\(_3\) in silica gels upon in-diffusion of CaCl\(_2\),\(^{30,34}\) and were also observed during growth from solution at high supersaturation.\(^{29}\) Taken together, it is obvious that Ba\(^{2+}\) and Sr\(^{2+}\) readily form biomorphs at ambient conditions, whereas Ca\(^{2+}\) “only” gives complex single crystals and/or mesocrystals. We now turn to consider changes in the growth behavior traced when gradually replacing Ba\(^{2+}\)/Sr\(^{2+}\) by Ca\(^{2+}\).

3.1.2. Effect of Added Ca\(^{2+}\) on the Growth Behavior of Silica-Witherite Biomorphs. Introducing Ca\(^{2+}\) to the mother solution of BaCO\(_3\) biomorphs proved to have a strong influence on the morphology of resulting precipitates. Visual observations show that for calcium molar fractions equal to or higher than 0.20, the samples become turbid soon after mixing (see Figure S1 in the SI), thus indicating significant Ca\(^{2+}\)-induced silica condensation also at lower cation concentrations. Again, crystallization occurred exclusively within the gel domains formed after some delay due to ongoing silica polymerization. Furthermore, the time required for crystals to be observed (ca. 3 days) was considerably longer than in the absence of Ca\(^{2+}\).

![Figure 2](image2.jpg)

**Figure 2.** Fractal architectures of (A,B) BaCO\(_3\) and (B,C) SrCO\(_3\), produced by continuous branching of an initial seed crystal along its \(c\)-axis (indicated by arrows), at first yielding dumbbell-like morphologies (A,C), which then develop into more or less closed spherulites (B,D). Note that these structures are precursors of the curved forms generated during the second stage of biomorph growth (however, not all of these particles give rise to characteristic polycrystalline aggregates, so some of them remain as “byproduct”). Scale bars: (A) 2 \(\mu m\), (B) 5 \(\mu m\), (C) 10 \(\mu m\), and (D) 20 \(\mu m\).

![Figure 3](image3.jpg)

**Figure 3.** FESEM images of fractal crystal aggregates grown from silica-containing mixtures of Ba\(^{2+}\) and Ca\(^{2+}\) at calcium molar fractions of (A) 0.02, (B,C) 0.10, (D,G) 0.20, (E,H) 0.50, and (F,I) 0.80. (C,G–I) Close-up views of the precipitates formed at distinct Ca\(^{2+}\) contents, revealing their microstructure. Increasing the calcium concentration first results in fairly large assemblies of blocky subunits (B), before nearly perfect (hemi)spherical structures are obtained at higher Ca\(^{2+}\) fractions (D–F). Scale bars: (A–F) 20 \(\mu m\), (inset of D) 50 \(\mu m\), and (C,G–I) 2 \(\mu m\).
(<10 h), and also the absolute number of particles was found to decrease with increasing $x_{Ca}$. Figure 3 illustrates the morphological evolution observed for mixtures of BaCl$_2$ and CaCl$_2$ at different molar fractions of Ca$^{2+}$. Drastic changes in the distribution of morphologies can be discerned already at calcium molar fractions as low as 0.02 (Figure 3A). In fact, there was not a single characteristic biomorph occurring throughout a series of syntheses at these conditions. Instead, fairly large conglomerates (up to 300 $\mu$m) of multiple intergrown fractal spherulites were observed. Individual units closely resemble those formed in Ca$^{2+}$-free experiments (cf. Figure 2), which suggests that the self-similar branching process (i.e., the first stage of morphogenesis) is not noticeably affected by the Ca$^{2+}$ ions. On the other hand, the fact that biomorphic ultrastructures were not at all formed indicates that the second stage of morphogenesis—i.e., coupled co-mineralization of silica and carbonate and their assembly into curved nano-crystalline aggregates—cannot be initiated even in the presence of only small amounts of calcium ions.

At a Ca$^{2+}$ fraction of 0.10, we could again only distinguish spherulitic objects, however with quite distinct appearance. Indeed, the observed crystal architectures consisted of rather thick, blocky subunits with widths in the range of 5 $\mu$m, which were arranged radially outward from a common origin (Figure 3B,C). Single subunits are identified as cyclic witherite twins, in which twinning occurs through the (110) planes.$^{37}$ Evidently, branching is less pronounced here than in the reference experiments without Ca$^{2+}$ (Figure 2) and at lower $x_{Ca}$ (Figure 3A), leading to structures with much smaller fractal dimensionality and larger subunits.

When the calcium content is further increased to 0.20 and 0.50 (Figure 3D,E), almost perfectly spheroidal aggregates with diameters of around 100 $\mu$m are obtained. Zooms onto the surface of the precipitates reveal ordered fiber-like subunits (Figure 3G,H) that emanate radially from the growth center and are about 1 $\mu$m wide, suggesting a high degree of fractal branching. Widely identical morphologies and textures were also observed when the amount of Ca$^{2+}$ exceeded that of Ba$^{2+}$ in the mixtures (i.e., at $x_{Ca} = 0.80$, Figure 3F,I). Bottom views of these structures further confirm the radial arrangement of the building units and moreover show that they are in fact hemispheres with an entirely flat bottom side (cf. Figure 3D,F).

This indicates that the original crystal seed was nucleated heterogeneously at the walls of the vessel and subsequently continued growing in direct contact with the interface, as in the case of the fractal precursors found in the reference experiments without Ca$^{2+}$ (cf. Figure 2B,D). However, in contrast to the latter, the core crystal did not attach to the walls via its lateral faces, but rather through its basal one (see below). Another main difference is that the hemispheres produced at these Ca/Ba ratios are considerably larger than the globules formed in the absence of calcium ions (100 $\mu$m vs 10 $\mu$m).

3.1.3. Effect of Added Ca$^{2+}$ on the Growth Behavior of Silica-Strontianite Biomorphs. Gradual replacement of Sr$^{2+}$ by Ca$^{2+}$ also led to clouding of the solutions after a certain induction period (up to about 1 h depending on the calcium concentration, cf. Figure S1 in the SI) and, for $x_{Ca} \geq 0.20$, resulted in the formation of a gel carpet on the bottom of the wells, where crystallization took place in the following. Typical morphologies observed as a function of increasing calcium content are illustrated in Figure 4. Unlike the experiments...
performed with mixtures of BaCl$_2$ and CaCl$_2$ (Figure 3), characteristic biomorphic aggregates like regular helicoids (Figure 4A) or worm-like braids (not shown) still occurred in the presence of 2 mol % Ca$^{2+}$. However, these structures were less frequent and seemed to be less developed as compared to counterparts grown from calcium-free solutions. At a Ca$^{2+}$ molar fraction of 0.10, merely clusters of interpenetrating globular units with sizes of about 200 μm were observed (Figure 4B), whereas twisted shapes typical for silica biomorphs remained absent. The raspberry-like form of these architectures is similar to fractal entities found during growth of BaCO$_3$ biomorphs at lower pH$^{14,20}$ and furthermore strongly resembles morphologies produced upon addition of sodium chloride (cf. Figure 8, below). Again, the data indicate that crystallization is terminated at the end of the fractal stage beyond a certain threshold in the calcium content (which is somewhat higher than in the BaCO$_3$ case), and that the dynamic interplay leading to noncrystallographic ultrastructures can no longer be initiated under these conditions.

Increasing the Ca$^{2+}$ concentration in the mother solution to molar fractions of 0.20 and 0.50 also gave exclusively fractal aggregates, which were smaller (ca. 100 μm, cf. Figure 4C,D) than those formed at x$_{Ca} = 0.10$ and differed to some extent in terms of their morphology. While precipitates grown at 20 mol % Ca$^{2+}$ were usually reminiscent of four-petalled clover sheets (Figure 4C), those obtained from solutions containing equal amounts of Sr$^{2+}$ and Ca$^{2+}$ proved to be perfect spheroids (Figure 4D). Both types of structures again evolved in contact with vessel walls, as is evident from their flat bottom sides (cf. Figure 4C). Close-up views of the texture of the aggregates disclose myriads of nanoscale subunits, either fibrous (Figure 4F) or platy (Figure 4G), thus supporting the notion of extensive fractal branching in mixed Sr$^{2+}$/Ca$^{2+}$ systems at intermediate molar ratios. Finally, at the highest calcium content investigated in this series (x$_{Ca} = 0.80$), the observed crystal morphologies (Figure 4E,H) were fundamentally distinct from those seen at lower Ca$^{2+}$ concentrations and rather resembled architectures found in the reference experiments with neat CaCl$_2$ solutions (Figure II–K).

### 3.2. Crystal Polymorphism and Composition

#### 3.2.1. EDX Analysis

Aggregates obtained from the experiments at different Ca$^{2+}$/Sr$^{2+}$/Ba$^{2+}$ contents were further examined with respect to their elemental composition as well as their crystalline modification and corresponding cell parameters. For this purpose, structures representative for each calcium concentration (according to Figures 3 and 4) were first analyzed by means of EDX spectroscopy. Figure 5 gives a plot of the measured Ca/Me ratios (where Me is the sum over the atom percentages detected for calcium and barium/strontium, i.e., Me = atom % Ca + atom % Sr/Ba) as a function of analytical fraction of Ca$^{2+}$ in solution. The data show the presence of noticeable amounts of Ca$^{2+}$ in the crystals already at low solution contents, suggesting that added calcium ions are incorporated into the mineralizing carbonate phase forming solid solutions (as verified by XRD, see below). Interestingly, a linear trend with fairly good correlation can be observed up to x$_{Ca} = 0.50$. This means that the amount of Ca$^{2+}$ included in the lattice of the mixed crystals directly scales with the analytical fraction in the mother liquor, indicating virtually complete miscibility of the distinct cations in the solid solution. Contrarily, at x$_{Ca} = 0.80$, the Ca/Me atomic fractions diverge from the linear trend toward higher calcium contents, especially in case of Ca$^{2+}$/Ba$^{2+}$ mixtures, where deviations are already visible at x$_{Ca} = 0.50$. In fact, hardly any barium seems to be incorporated into the forming crystals at x$_{Ca} = 0.80$ (Ca/Me = 0.97), whereas strontium and calcium still exhibit somewhat higher miscibility at these ratios (Ca/Me = 0.90). Most likely, this result can be ascribed to smaller differences in the ionic radius between Sr$^{2+}$ and Ca$^{2+}$ (1.45 vs 1.32 Å, coordination number (CN) = 9) as compared to Ba$^{2+}$ and Ca$^{2+}$ (1.61 vs 1.32 Å, CN = 9).40

The silica content of the aggregates, given as the Si/Me atomic ratio, was found to be on the same order of magnitude (generally <0.10, in most cases <0.05) for all of the various fractal structures produced under different conditions (see Table S1 in the SI). The obtained values thus are similar to silica levels reported for the globular clusters occurring during the first stage of morphogenesis in silica-witherite biomorphs.23 Since their formation is based on crystal growth poisoning by a non-absorbable impurity (silica), which is constantly pushed ahead by the growing front and not noticeably incorporated,16,41 the resulting architectures contain very little silica (as observed). This explains the low count rates for Si in the EDX spectra and furthermore confirms that the distinct spheroidal forms shown in Figures 3 and 4 have been generated by fractal branching at noncrystallographic angles.

#### 3.2.2. X-ray Diffraction

Diffraction patterns recorded from powdered samples (Figure 6) demonstrate that the alkaline-earth carbonates crystallize in aragonite-type lattices (virtually phase-pure, no other peaks observed) up to certain molar fractions of Ca$^{2+}$ in the mother solutions, which differ depending on whether Sr$^{2+}$ or Ba$^{2+}$ is used.

In the case of strontium, the forming aggregates favor an orthorhombic phase up to 50 mol % Ca$^{2+}$ (Figure 6A–E), whereas only up to 20 mol % can be included into the corresponding witherite/aragonite lattice (Figure 6H–K). Moreover, with increasing calcium content, reflections are shifted toward higher 2θ values (illustrated for the (111) peak by the red line in Figure 6A–E and H–K) due to the incorporation of the smaller Ca$^{2+}$ ion into the strontianite/witherite structure (lattice contraction). This confirms the formation of mixed alkaline-earth carbonate lattices, i.e., solid solutions, in line with the EDX data. To extract the lattice parameters of these mixed crystals, the XRD patterns were further analyzed and fitted by means of the least-squares minimization method. Cell volumes resulting for the distinct calcium molar fractions are plotted in Figure 7. For both

![Figure 5](dx.doi.org/10.1021/cg5004116/Cryst.Growth.Des.2014,14,6177–6188)
strontium and barium carbonate, the volume of the unit cell decreases linearly with increasing $x_{Ca}$, as a consequence of the integration of the small Ca$^{2+}$ cation into the orthorhombic lattice.42 Thereby, the decline of the cell volume is obviously much steeper in the case of calcium/barium mixtures, due to the larger difference in the ionic radii of Ba$^{2+}$ and Ca$^{2+}$ as already mentioned above, leading to stronger contraction. When $x_{Ca}$ is increased to 0.80 in Ca$^{2+}$/Sr$^{2+}$ systems, calcite is the only polymorph, and there are no more reflections of aragonite-type carbonates discernible in the patterns (Figure 6F), in line with the morphological change traced at these Ca$^{2+}$ fractions (cf. Figure 4D,E). Comparison of the lattice parameters obtained for the particles in the absence of strontium (Figure 6G) and at $x_{Ca}=0.80$ (Figure 6F) suggests a slight shift in the $a/c$ ratio to lower values (from 0.2923 to 0.2908), presumably owing to the inclusion of the larger Sr$^{2+}$ ions into the rhombohedral lattice, as reflected in the EDX data (ca. 10 atom % incorporated Sr) and also reported in previous studies.37,43

Similar behavior is observed at $x_{Ca}=0.50$ for mixtures of Ca$^{2+}$ and Sr$^{2+}$ (Figure 6L). However, due to the higher amount of barium in the mother solution, significantly more Ba$^{2+}$ is incorporated into the calcite structure (up to 43 atom % according to EDX). This, together with the size of the barium cations, leads to a much more pronounced change of the $a/c$ ratio in this case (from 0.2923 to about 0.2854). Most surprisingly, we find that, for a Ca$^{2+}$ molar fraction of 0.80 (Figure 6M), vaterite is the exclusive crystalline phase present in the samples. This is clearly unexpected because vaterite is metastable under the given conditions, and calcite was obtained at both lower (Figure 6L) and higher (Figure 6N) calcium content. In order to rule out subtle kinetic effects and issues of sample preparation, this experiment was repeated multiply, each time yielding vaterite as the predominant polymorph. As the EDX data indicate only traces of barium in the crystals (cf. Figure 5), it seems as if Ba$^{2+}$, in mixtures with Ca$^{2+}$ at these particular ratios, is somehow able to stabilize vaterite in solution. Furthermore, it is intriguing to note that the hemispherical structures shown in Figure 3D−F all consist of different polymorph (aragonite, calcite, and vaterite, respectively), despite their close morphological and textural similarities.

### 3.3. Effect of Ionic Strength on the Growth Behavior of Silica-Witherite Biomorphs

The above data illustrate that addition of Ca$^{2+}$ to mother solutions of silica-witherite and silica-strontianite biomorphs can drastically influence the final morphologies. A possible explanation for this behavior is based on specific ion effects, that is, the harder calcium ions interact much more strongly with silicate ions than their softer higher homologues Sr$^{2+}$ and Ba$^{2+}$, thereby inducing silica polycondensation via charge screening. In this way, the speciation of silica may be dramatically altered in solution and self-assembly can no longer proceed beyond the initial stage of fractal branching. However, if the main role of added Ca$^{2+}$ is to

---

**Figure 6.** Powder XRD patterns of precipitates isolated after crystallization of alkaline-earth carbonates from dilute silica sols containing different amounts of Ca$^{2+}$ and either Sr$^{2+}$ (left) or Ba$^{2+}$ (right). The molar fraction of Ca$^{2+}$ ions in the samples was gradually increased as (A,H) 0, (B,I) 0.02, (C,J) 0.10, (D,K) 0.20, (E,L) 0.50, (F,M) 0.80, and (G,N) 1.00. Notation: C, calcite; V, vaterite; A, aragonite; S, strontianite; W, witherite.

**Figure 7.** Cell volumes of orthorhombic solid solutions formed upon co-precipitation of CaCO$_3$ and (black squares) SrCO$_3$ or (red circles) BaCO$_3$ from alkaline solutions in the presence of silica and at distinct Ca$^{2+}$ molar fractions. Values were derived by least-squares minimization of the XRD patterns shown in Figure 6. In both cases, the cell volume decreases linearly as the smaller calcium ions become incorporated into the orthorhombic crystal system. Fits to the data (full lines) give slopes of $-25.25$ (Å$^3$/x$_{Ca}$) ($R^2 = 0.996$) and $-82.83$ (Å$^3$/x$_{Ca}$) ($R^2 = 0.989$) for CaCO$_3$/SrCO$_3$ and CaCO$_3$/BaCO$_3$ solid solutions, respectively.

---

6183
screen the charges of silicate species and thus facilitate their condensation, then simple electrolytes like sodium chloride should have a similar impact on morphogenesis at sufficiently high concentrations (because the Debye screening length decreases with growing ionic strength). To test this hypothesis, we have performed additional experiments in which attempts were made to grow BaCO₃ biomorphs from solutions containing different amounts of excess salt (NaCl; Figure 8).

![Figure 8. BaCO₃ crystal aggregates grown from alkaline silica-containing solutions, to which (A) 50 and (B–D) 250 mM of excess NaCl had been added. Scale bars: (A,B) 100 μm, (C) 30 μm, and (D) 3 μm.](image)

First distinct effects could be noted at a salt concentration of 50 mM, where no more sheets and helicoids were formed. Instead, globular particles and colony-like clusters of interpenetrating spheroids were observed (Figure 8A).

Frequently, worm-like structures were seen to emerge from these clusters and grow to lengths of often more than 100 μm. Starting from a NaCl content of 100 mM, even worms were absent and none of the polycrystalline morphologies characteristic of biomorphs remained. Instead, exclusively fractal architectures with diameters around 200 μm were found after growth was completed (Figure 8B), typically displaying raspberry-like shapes (Figure 8C). As already discussed above, these structures arise from splitting of an initial BaCO₃ single crystal and subsequent self-similar ramification, as is evident from close-up views of their surface (Figure 8D), which reveal myriads of nanoscale projections and hence again suggest a large degree of branching. Fractal aggregates with similar raspberry-like morphologies, but smaller dimensions (∼30 μm), were reported to occur in samples at pH 10 where, likewise, no distinct biomorphic shapes could be generated.¹⁴,²⁰,⁶⁶ Thus, excess salt is obviously capable of influencing morphogenesis in a way that is comparable to what has been observed in the presence of Ca²⁺ ions (cf. Figure 4B), as expected. However, to achieve this, drastically higher concentrations of monovalent ions are required (100 mM NaCl vs 0.1 mM Ca²⁺). Under these conditions, the reaction mixtures indeed showed similar turbidity as in the case of the dilute Ca²⁺-containing solutions, indicating ongoing silica coagulation. This behavior is well-known in the literature and can be ascribed to the bridging ability of divalent cations, which greatly enhances their coagulation power (that scales with the sixth power of the ion charge according to the Schulze–Hardy rule). EDX analyses of the precipitates do not show significantly increased counts of Na or Cl (even at a very high excess of salt), while XRD data confirm the crystalline phase to be pure witherite (see Figure S2 in the SI). These results further corroborate that the added ions do not interact directly with the crystallizing carbonate phase, but rather affect the growth process indirectly by influencing the silica in solution.

4. DISCUSSION

4.1. Prevention of Biomorph Formation in the Presence of Ca²⁺ Ions. The results obtained from experiments with mother solutions containing mixtures of different alkaline-earth cations have shown that the presence of Ca²⁺ leads to substantial changes during crystallization and prevents the formation of silica biomorphs already at very low concentrations. The most obvious discrepancy between samples with and without added calcium is that the otherwise transparent solutions turn turbid within minutes as soon as Ca²⁺ is present. The colloidal particles (and polymeric solutes) formed at this stage consist of amorphous silica with minor amounts of entrapped or surface-bound Ca²⁺. With time, these silica colloids sediment toward the bottom of the crystallization wells, where they accumulate and eventually cross-link to build up a layer of silica gel (cf. Figure S1 in the SI), in which growth of carbonates occurs after some delay. These observations demonstrate that calcium ions can catalyze silica polycondensation and coagulation processes by screening repulsive charges much more efficiently than Sr²⁺ and Ba²⁺, as reported also in previous work.⁴⁹–⁵¹ This can presumably be attributed to the lower charge density of cations with larger size and may be considered a direct manifestation of specific ion effects.⁵²

Reinforced condensation in solution will cause the distribution of silicate species to shift toward higher oligomers, long before any carbonate mineralization has commenced. Thus, crystallization will occur under conditions where the actual concentration of silicate monomers and dimers—which likely represent the active species during growth of biomorphs—is significantly decreased. An apparent consequence of these circumstances is that morphogenesis ceases at the end of the initial fractal route and the system cannot pass into the second stage of chemically coupled co-precipitation and polycrystalline growth. Most probably, this is because considerable amounts of silica were already coagulated independent of carbonate crystallization, so that critical supersaturation levels required for local polymerization and coating of carbonate nanocrystals are no longer accessible.¹² Therefore, the dynamic pH-based interplay between silica and carbonate—which occurs only within a certain window of bulk conditions—cannot be maintained, rendering concerted self-assembly of complex morphologies impossible. In this regard, direct interactions between Ca²⁺ and silicate, which can be considered negligible in case of Sr²⁺ and Ba²⁺, preclude the formation of biomorphs in these systems.

The notion that enhanced silica condensation prevents growth of curved structures has been confirmed by further experiments in the presence of sodium chloride, used as background electrolyte to vary the ionic strength. Indeed, similar effects were found in terms of the occurring morphologies (i.e., only fractal structures and no more biomorphic shapes); however, drastically higher concentrations of monovalent ions (≥100 mM NaCl) were needed to induce
changes comparable to those observed for minor contents of divalent Ca\[^{2+}\]. Thus, high ionic strengths progressively shield the negative charges of silicate species, thereby favoring their oligomerization\(^3\) and ultimately resulting in the formation of raspberry-like architectures, instead of biomorphs. A second potential explanation for the distinct growth behavior at elevated salinity refers to the supply of the system with carbonate ions. In fact, large amounts of salt depress the rate of CO\(_2\) uptake by the solutions due to a decrease of its solubility in water (which obviously does not apply for experiments with added Ca\[^{2+}\] ions).\(^5,\)\(^3\) In order to trigger and maintain coupled co-precipitation, sufficient bulk concentrations of carbonate species are needed over extended periods of time. This criterion may not be met in media at high ionic strength, and furthermore has proven to be one of the key parameters for the morphological selection at lower pH.\(^14,\)\(^20\) In this sense, both the silica and (time-dependent) carbonate speciation seem to be inappropriate for self-assembly in concentrated NaCl solutions.

In mixtures of calcium and barium, Ca\[^{2+}\]/Sr\[^{2+}\] molar fractions as low as 0.02 were sufficient to hinder the formation of biomorphs, lending support to the notion that the cations primarily act in a catalytic way. By contrast, biomorphs were still obtained in Ca\[^{2+}\]/Sr\[^{2+}\] systems at the same composition. In principle, this behavior is counterintuitive, as Sr\[^{2+}\] is harder than Ba\[^{2+}\] and thus should more efficiently support Ca\[^{2+}\] in provoking silica polycondensation. We can only speculate about possible reasons for this finding, but it seems all the more clear that specific ion effects play an important role in these systems. For example, one may argue that the competition of the distinct cations for interaction sites at the silica is the decisive factor in this context. That is, Sr\[^{2+}\] is more readily capable of displacing Ca\[^{2+}\] at silicate groups than Ba\[^{2+}\], thus decreasing the overall tendency for coagulation. In other words, the barium cations leave all interaction potential open to Ca\[^{2+}\], whereas Sr\[^{2+}\] behaves as a true competitor. This idea is supported by dynamic light scattering measurements, which demonstrate that cation-induced silica condensation is faster in calcium–barium than in calcium–strontium mixtures (see Figure S3 in the SI). An alternative scenario is based on the fact that, at lower calcium fractions (\(x_{\text{Ca}} \leq 0.2\), cf. Figure S), more Ca\[^{2+}\] is incorporated into the lattice of Sr\(\text{CO}_3\) than in Ba\(\text{CO}_3\) (e.g., 1.09 atom % Ca in Sr\(\text{CO}_3\) vs. 0.51 atom % Ca in Ba\(\text{CO}_3\) at \(x_{\text{Ca}} = 0.02\)). Consequently, less free calcium ions would then be available in solution for cation-induced silica condensation, allowing biomorphs to grow in Ca\[^{2+}\]/Sr\[^{2+}\] mixtures up to a calcium molar fraction of 0.02.

Another interesting observation is that added Ca\[^{2+}\] ions retard carbonate crystallization, such that the growth period had to be increased to 3 days (instead of about 12 h in case of pure wetherite and strontianite biomorphs). As already mentioned, the pH of the solutions and its variations over time did not noticeably change with the calcium content. This implies that the temporal profiles of the actual carbonate concentration should be similar in all systems and, hence, that the free amount of alkaline-earth cations is lower in Ca\[^{2+}\]-containing mixtures. These considerations suggest that Ca\[^{2+}\] along with Sr\[^{2+}\] or respectively Ba\[^{2+}\] ions are temporarily bound to (likely polymeric) silicate species or rather the gel matrix deposited on the bottom of the vials. As a result, the supersaturation of the alkaline-earth carbonates may be decreased as compared to the pure systems, leading to longer growth times. We note, however, that the lower bulk supersaturation could as such be an important limiting factor for the ability of biomorphs to form under the particular circumstances, as described in detail in a recent study.\(^14\)

Decelerated crystallization in the presence of Ca\[^{2+}\] could to some extent also be due to differences in the solubility of the orthorhombic alkaline-earth carbonates (\(pK_{\text{SP}}\) = 8.34 for Ca\(\text{CO}_3\), 9.27 for Sr\(\text{CO}_3\), and 8.56 for Ba\(\text{CO}_3\) at 25 °C.\(^3,\)\(^4,\)\(^5,\)\(^6\)) Thus, aragonite is more soluble than strontianite and wetherite, and might therefore slow down growth rates for mixed crystals at a given level of ion concentrations.

A final aspect that may contribute to the lack of biomorphs already at low Ca\[^{2+}\] fractions is related to the surface energies and structures of the mixed alkaline-earth carbonate crystals. Recently, Aquilano and co-workers proposed that adsorption of silica on Ba\(\text{CO}_3\) nanoparticles (and hence their stabilization) is promoted by epitaxial matching of silicate chains on the carbonate surfaces, which was demonstrated for witherite on α-quartz and inferred for the inverse case.\(^3,\)\(^5,\)\(^7\) Silica adsorption was suggested to reduce the interfacial tension of the carbonate particles and consequently increase nucleation rates, which was considered to be crucial for the formation of biomorphs. Inclusion of Ca\[^{2+}\] into the wetherite (and strontianite) lattice could possibly impair the above-mentioned epitaxial matching and therefore, the nucleation rate of mixed carbonate crystals may not be high enough to sustain the growth of biomorphs.

### 4.2. Fractal Branching at Different Ca\[^{2+}\]/Sr\[^{2+}\] and Ca\[^{2+}\]/Ba\[^{2+}\] Ratios.

Apart from the fact that biomorphs cannot grow already in the presence of minor amounts of Ca\[^{2+}\], our data further demonstrate that various fractal structures are generated over a wide range of compositions. At low calcium contents (\(x_{\text{Ca}} \leq 0.02\) for Ba and \(x_{\text{Ca}} \leq 0.1\) for Sr), these branched architectures are widely identical to those produced in the absence of Ca\[^{2+}\] and typically adopt either dumbbell-like or spherulitic shapes (cf. Figure 2). In many cases, several of these fractal spheroids bundle to build networks (Figure 3A), or grow together yielding architectures with raspberry- or cauliflower-like appearance (Figure 3B and Figure 8). However, a commonality of all these forms is that they arise from a seed crystal, which was nucleated heterogeneously with its long axis parallel to the underlying substrate, as is evident from corresponding bottom views (cf. Figure 2). In fact, nucleation appears to occur on the lateral faces of the pseudohexagonal rod, that is, on either (011) or (020). Splitting at both ends and subsequent bifurcation then inevitably results in dumbbell-like intermediates, which later may be closed to give (notched) spheres. These circumstances are illustrated schematically in Figure 9A–C. Above a certain threshold in the molar fraction of Ca\[^{2+}\] (\(x_{\text{Ca}} \geq 0.1\) for Ba and \(x_{\text{Ca}} \geq 0.2\) for Sr), the morphological variety of the observed fractal patterns becomes strongly restricted. Essentially, most of the precipitates display (more or less perfect) hemispherical shapes (cf. Figure 3B–F and Figure 4C,D) and microstructures that are characterized by numerous nanometric projections arranged radially outward from the center of the hemisphere (cf. Figure 3G–I and Figure 4F,G). In this context, the crystals produced from Ca\[^{2+}\]/Ba\[^{2+}\] mixtures at \(x_{\text{Ca}} = 0.10\) (Figure 3B,C) are an exception, because they are hardly branched and rather consist of partially intergrown micrometer-sized subunits, for reasons that shall not be further discussed here. The formation of hemispherical structures at higher calcium content can be understood when inspecting the flat bottom sides of the aggregates, which were in contact with an interface during both nucleation and growth. In corresponding images (especially Figure 3D), the seed crystal
transition from the distinct fractals found with no or little added over (011) and (020). This might also explain why the alters the relative surface energies of the di remains to be discussed. In agreement with previous studies,58 aggregates obtained under the various investigated conditions Calcium BaCO3 and SrCO3, respectively). Accordingly, the unit cell mineral phases (as detected by EDX and XRD, cf. Figures 5). In strontium-containing systems, a switch in polymorphism state directly correlates with that in the mother solution (Figure 10 atom % (Figure 5) and thus about half of the initial solution content. Consequently, Sr2+ integration into calcite is not as favorable as Ca2+ substitution into strontianite, a result that is in line with the literature, where Sr2+ was found to substitute Ca2+ in calcite merely to minor degrees.45,46,48–51 In the case of Ca2+/Ba2+ mixtures, the situation is more complicated. First, it can be noted that mixed orthorhombic phases occur only up to 20 mol % Ca2+, presumably because of the larger difference in cation size and greater structural mismatch. At xCa = 0.50, the forming crystals therefore prefer a calcitic modification (cf. Figure 6L), into which Ba2+ ions are included in fractions as high as 0.43. This challenges values reported in earlier work, which were considerably lower.45,60,62,63 Indeed, partition coefficients determined for Sr2+ and Ba2+ in calcite based on the present experiments (Dcalcite = 0.48 at xCA = 0.80 and Dcalcite = 0.86 at xCA = 0.50) exceed those obtained previously by factors ranging from 5 to 45 (D ≈ 0.03–0.08 and 0.02–0.03 for Sr2+ and Ba2+, respectively, in calcite).64,66 Although we cannot explain this unexpected discrepancy, one may speculate that the presence of silica in the mother solutions could somehow promote incorporation of the larger alkaline-earth cations into calcite.

Increasing the Ca2+ molar content to 0.80 in calcium–barium systems led to the—likewise unexpected—observation of vaterite being the exclusive crystalline phase detected (Figure 6M). EDX analyses of these crystals have shown that they include only traces of barium (ca. 0.5 atom %). This complies well with data reported by Brecevic et al., who concluded that absorption of Ba2+ into the vaterite lattice causes distortion (due to larger cation radius) and therefore is strongly limited.66,67 However, these low amounts of foreign ions appear to be effective in stabilizing vaterite against energetically favored transformation to calcite, possibly in cooperation with the silicate species in solution.

Last but not least, it is remarkable that the gradual changes in polymorphism, traced when raising the calcium content in mixtures with barium from 0.2 over 0.5 to 0.8, are not at all reflected in the resulting morphologies and structures, given that hemispheres of similar sizes were formed at all three compositions (Figure 3D–F) and also the constituting nanoscale subunits looked widely identical (cf. Figure 3G–I). Nonetheless, as outlined above, these architectures can obviously consist of any of the three anhydrous polymorphs of calcium carbonate, i.e., aragonite (xCa = 0.20), calcite (xCa = 0.50), and vaterite (xCa = 0.80). This is of particular interest when considering that these aggregates are supposedly generated by progressive branching of an initial core crystal, and that the habit of this seed crystal should be different for the three polymorphs (rod for aragonite, rhombohedron for calcite, and presumably sphere for vaterite). Current studies are therefore focused on investigating the early stages of crystallization in these systems and elucidating the nature of the core crystal formed by the distinct phases.

5. CONCLUSIONS

In this work, we have studied the crystallization of alkaline-earth metal carbonates from silica-containing solutions at high pH, gradually replacing Ba2+ or respectively Sr2+ by Ca2+ in mixtures of the corresponding chloride salts. Our results clearly demonstrate that even minor amounts of calcium ions can strongly interfere with the growth behavior otherwise observed for witherite and strontianite under the influence of silica in the absence of Ca2+. In particular, the formation of complex curved morphologies is fully prevented as soon as a certain threshold for Sr2+ and Ba2+, respectively, in calcite). Finally, the polymorphism of the cation during the following stages of growth leads to hemispherical entities as indicated in Figure 9E, whereas no dumbbell-like intermediates are observed under these circumstances. A possible reasoning for this change in the nucleation behavior is that incorporation of Ca2+ into the mineral phases (as detected by EDX and XRD, cf. Figures 5–7) alters the relative surface energies of the different crystallo-graphic faces, rendering nucleation through (001) favorable over (011) and (020). This might also explain why the transition from the distinct fractals found with no or little added Ca2+ to the hemispheres occurs at higher calcium contents in Ca2+/Sr2+ mixtures than in Ca2+/Ba2+ systems, since changes in the structure and surface energies (with respect to the pure phases) are expected to be greater when incorporating calcium in the lattice of witherite (Ba2+ being larger than Sr2+).

4.3. Polymorph Selection in Calcium–Strontium and Calcium–Barium Mixtures. Finally, the polymorphism of the aggregates obtained under the various investigated conditions remains to be discussed. In agreement with previous studies,58 we find that the alkaline-earth carbonates form orthorhombic solid solutions with virtually complete miscibility of phases over a wide range of compositions (0–20 and 0–50 mol % Ca2+ for BaCO3 and SrCO3, respectively). Accordingly, the unit cell volume of the resulting crystals decreases linearly with increasing calcium content due to progressive lattice contraction (cf. Figure 7), while the fraction of Ca2+ in the solid state directly correlates with that in the mother solution (Figure 5). In strontium-containing systems, a switch in polymorphism is observed only at an excess of calcium (xCa = 0.80), where calcite proved to be the only crystalline modification generated. A shift in the corresponding XRD peak positions toward lower angles (Figure 6F,G) indicates significant incorporation of Sr2+ into the rhombohedral lattice, which was determined to be ca. 10 atom % (Figure 5) and thus about half of the initial solution content. Consequently, Sr2+ integration into calcite is not as favorable as Ca2+ substitution into strontianite, a result that is in line with the literature, where Sr2+ was found to substitute Ca2+ in calcite merely to minor degrees.45,46,48–51 In the case of

Figure 9. Schematic representation of the fractal growth mechanisms envisaged for lower (A–C) and higher (D–F) calcium fractions. Note that structures are not drawn to scale.
i.e., dissolved silicate species. Charge screening by the cations catalyzes silica polycondensation, shifting its speciation toward higher oligomers and eventually inducing coagulation. This leads to circumstances where the chemistry and/or concentration of the relevant components in solution are no longer suitable for dynamically coupled co-mineralization to be initiated. In this regard, it seems as if the failure to produce calcium carbonate-based silica biomorphs at ambient conditions is not solely due to crystal polymorphism (i.e., because CaCO₃ favors calcite over aragonite) but also—and probably for the most part—originates from specific ion effects related to the different polarity of the alkaline-earth cations, which govern their competition for interaction with the silica in solution. This notion is supported by the observation that mixed CaCO₃/SrCO₃ and CaCO₃/BaCO₃ particles, as obtained over a wide range of metal ion ratios, did not assemble into biomorphic ultrastructures (unlike corresponding mixtures of SrCO₃ and BaCO₃), even when their crystal phase was confirmed to be an orthorhombic aragonite-type solid solution. Thus, the only conceivable way to enable true bottom-up self-organization of CaCO₃ biomorphs (no seeding or the like) from dilute sols at room temperature—as observed for both SrCO₃ and BaCO₃—would be to deliberately avoid or reduce ionic interactions between Ca²⁺ and silicate ions in solution, which, in our opinion, is practically impossible.

Instead of complex sinuous morphologies, co-precipitation of the alkaline-earth carbonates and silica afforded a wealth of different fractal structures, all of which contained the distinct metal cations in ratios corresponding more or less to those prevailing in the mother liquor (complete miscibility for orthorhombic solid solutions, lower partitioning of Sr²⁺ and Ba²⁺ into vaterite and calcite). Further parameters such as the BaCO₃ between Ca²⁺ and silicate ions in solution, which, in our view, would be to deliberately avoid or reduce ionic interactions between Ba²⁺ under particular conditions (i.e., at a Ca/Ba ratio of 4:1), virtually identical structures (micrometer-sized hemi-braids subunits) can be generated on the basis of either of the three anhydrous ultrastructures (unlike corresponding mixtures of SrCO₃ and Ca/Ba crystal aggregates (Table S1), EDX and XRD data of structures grown at high ionic strength (Figure S2), and DLS data of silica polycondensation in Ca/Sr and Ca/Ba mixtures (Figure S3).
