We report on the observation of cyclotron-resonance-induced photocurrents, excited by continuous wave terahertz radiation, in a three-dimensional topological insulator (TI) based on an 80-nm strained HgTe film. The analysis of the photocurrent formation is supported by complementary measurements of magnetotransport and radiation transmission. We demonstrate that the photocurrent is generated in the topologically protected surface states. Studying the resonance response in a gated sample, we examined the behavior of the photocurrent, which enables us to extract the mobility and the cyclotron mass as a function of the Fermi energy. For high gate voltages, we also detected cyclotron resonance (CR) of bulk carriers, with a mass about two times larger than that obtained for the surface states. The origin of the CR-assisted photocurrent is discussed in terms of asymmetric scattering of TI surface carriers in the momentum space. Furthermore, we show that studying the photocurrent in gated samples provides a sensitive method to probe the cyclotron masses and the mobility of two-dimensional Dirac surface states, when the Fermi level lies in the bulk energy gap or even in the conduction band.

I. INTRODUCTION

The physics of relativistic Dirac fermions in semiconductors has recently moved into the focus of modern research, due to their unique properties and promising novel applications (for recent reviews, see [1–6]). Among diverse systems addressed in the literature, HgTe-based structures represent an extraordinary material class, allowing the fabrication of a high-quality material [7–12] with Dirac-type systems of different forms. The latter includes topological protected edge and surface states of two- and three-dimensional topological insulators [13–26], quantum wells (QWs) with critical thickness [13,27–34], and bulk HgCdTe material at the point of semiconductor-to-semimetal transition [35]. Three-dimensional (3D) topological insulators (TIs) based on strained HgTe films [18] are of particular interest. Indeed, in these materials strain opens a gap in the otherwise gapless HgTe, which together with the high quality of the material allows one to obtain insulation in the bulk and to study electron transport in surface states only [18,24]. This differs significantly from all other known 3D TIs (e.g., Bi2Te3, Sb2Te3), where dc electron transport is (almost always) hindered by the high residual carrier density in the bulk [36–38]. This unique property allows one to observe the quantum Hall effect [18] and Shubnikov–de Haas oscillations [24] in strained HgTe film and, thus, to analyze surface-state transport in TIs. Furthermore, the negligible contribution from bulk carriers opens a way to study Dirac fermions in a 3D TI by cyclotron resonance measured via transmission or Faraday effect [39–41] and, as we show in the following, terahertz (THz) radiation-induced photocurrents.

II. SAMPLES

The experiments are carried out on molecular beam epitaxy grown high-mobility 80-nm-thick HgTe films. The HgTe film is sandwiched between thin Cd0.66Hg0.33Te layers acting as capping (top) and buffer (bottom) layers. The cross section of the structure is shown in Fig. 1(a). The structure is grown on a GaAs substrate with (013) surface orientation covered by a thin ZnTe layer and 4-μm-thick CdTe layer. The CdTe layer is fully relaxed because of its large thickness. The Cd-HgTe/HgTe/CdHgTe layers grown on top adopt the underlying CdTe lattice constant. The lattice mismatch between HgTe and CdTe of about 0.3% results in a tensile strain in the HgTe film, which opens a topological gap [15,16,18]. The evidence for...
FIG. 1. (Color online) (a) Cross section of the investigated structures. (b) An x-ray reciprocal space map near the asymmetric (113) reflection. The diffracted intensity is plotted on a color-coded logarithmic scale. The CdTe film is relaxed with respect to the GaAs substrate because the line connecting their maxima points to the origin of the reciprocal space. The HgTe and CdHgTe films are fully strained with respect to the CdTe, as their peaks lie on a straight line along the z axis perpendicular to the sample surface (r. l. u.:– reciprocal lattice unit).

substantial strain in our samples comes from x-ray diffraction measurements, shown in Fig. 1(b). Note that such a sandwich design of the structure reduces the influence of dislocations caused by the lattice mismatch [24] and allows one to obtain high electron mobilities (up to $4 \times 10^5$ cm$^2$/V s at 40 K) together with low residual bulk impurity concentration (about $10^{16}$ cm$^{-3}$ as estimated for ungated samples).

Several kinds of gated and ungated samples have been prepared from the same wafer, including ungated square-shaped samples of $4 \times 5$ mm size [see Fig. 2(a)], gated (ungated) cross-shaped structures [see Fig. 2(b)], and gated Hall-bar samples. On the square-shaped samples we have fabricated four Ohmic contacts in the middle of the edges. The sample edges are oriented along $x \parallel [100]$ and $y \parallel [03\bar{1}]$. The samples of this kind have been used for simultaneous transmission and photocurrent measurements. In order to study photocurrents and magnetotransport as a function of the Fermi level position, we have fabricated gated structures. To avoid insulator leakages, we have used small area cross-shaped structures with four Ohmic contacts [Fig. 2(b)]. The structures of 50-μm width and 1500-μm length have been patterned by means of standard photolithography and wet etching. Semitransparent Ti/Au gates of 20-nm/5-nm thickness and 1500-μm diameter have been deposited on 100 nm SiO$_2$ and 200 nm of Si$_3$N$_4$ dielectric layer grown by chemical vapor deposition. To monitor the influence of the gates on the CR position, we have used both gated as well as ungated cross structures. Gates have also been deposited on Hall-bar samples, which have been used primarily for magnetotransport experiments.

Samples have been characterized by magnetotransport measurements using standard low-frequency lock-in technique with the currents in the range of 0.1–1 μA and with the magnetic field $B$ up to 7 T applied normal to the HgTe film plane. The measurements of $\rho_{xx}(B)$ and $\rho_{xy}(B)$ for the ungated sample at $T = 4.2$ and 40 K are presented in Figs. 3(a) and 3(b). The obtained $\rho_{xx}(B)$ shows a large positive magnetoresistance and the Hall resistance $\rho_{xy}(B)$ exhibits a nonlinear $N$-type shape around $B = 0$ T, both of which are typical for a...
emitting radiation with frequency $f$ states into the conduction band. The tuned from the valence band through the Dirac-type surface gated samples. By means of a top gate, the Fermi energy was attributed to the surface topological states. situated in the valence band while the observed electrons are of holes at low temperatures indicates that the Fermi level is.

To support this conclusion, we studied magnetotransport in gated samples. By means of a top gate, the Fermi energy was tuned from the valence band through the Dirac-type surface states into the conduction band. The $\rho_{xx}(U_g)$ dependence obtained at $T = 4.2$ and 40 K is presented in Fig. 3(e), showing that the low-temperature resistivity has a maximum near $U_g \approx -0.8$ V. At the same gate voltage, the Hall resistivity $\rho_{xy}$ changes its sign at $B = 1$ T [see Fig. 3(b)]. The analysis of the data, carried out following Ref. [24], delivers a self-consistent picture of the gate-controlled transition between a hole metal to a topological insulator and, finally, at large positive gate voltages, to an electron metal. The edges of the bulk bands are well defined; see arrows marked “$E_v$” and “$E_c$” in Fig. 3(e) for valence and conduction band edges, respectively. In the whole range of $U_g$, corresponding to the Fermi level situated in the valence band, one observes a large positive magnetoresistance accompanied by a nonlinear (N-shaped) $\rho_{xx}(B)$, which changes sign. This indicates that both electrons and holes contribute to transport and the results can be nicely fitted by a two-carrier Drude model (see Ref. [24]). The electron and hole 2D densities of bulk and surface states as a function of $U_g$ are shown in Fig. 3(f). The same transport signatures have been observed for the ungated samples [see Figs. 3(a) and 3(b)], indicating that the Fermi level is situated in the valence band as well. When the Fermi level is in the valence band, the conduction band is about 15 meV (energy gap) above so that at 4.2 or 40 K the thermal occupation of the conduction band states is small. Therefore, only surface electrons contribute for these gate voltages and temperatures to transport. Note that at high temperatures electrons populate surface as well as bulk states. Figure 3(d) shows that both, electron and hole, mobilities decrease with increasing temperature. We emphasize that the electron mobility remains as high as $10^5$ cm$^2$/V s even at $T = 40$ K.

This indicates that gate fabrication does not change the band diagram of the structure qualitatively but only introduces a built-in electric field due to, e.g., charged impurities and/or defects. The defect density can be estimated as $(1 \div 2) \times 10^{11}$ cm$^{-2}$, varying from sample to sample.

For photocurrent excitation and cyclotron-resonance transmission measurement we apply a cw molecular laser [42,43] emitting radiation with frequency $f = 2.54$ THz (wavelength $\lambda = 118$ $\mu$m), $f = 1.62$ THz ($\lambda = 184$ $\mu$m), and $f = 0.69$ THz ($\lambda = 432$ $\mu$m). The incident power $P \approx 10$ mW is modulated at about 180 Hz by an optical chopper. Structures were placed in a temperature variable optical cryostat with $z$-cut crystal quartz windows. The radiation at normal incidence is focused onto a spot of about 1.5-mm diameter at the center of the sample. The spatial beam distribution has an almost Gaussian profile, measured by a pyroelectric camera [44,45]. The initial linear polarization can be transformed into right- ($\sigma^+$) and left- ($\sigma^-$) circularly polarized light by applying a $\lambda/4$ plate. A magnetic field $B$ up to 7 T is applied normal to the film. The photosresponse is measured applying standard lock-in technique, either as a photocurrent $I_{x,y}$ or the corresponding photovoltage $U_{x,y}$ picked up across 50 $\Omega$ or 10 M$\Omega$ load resistors, respectively. Parallel to the photocurrents we also studied radiation transmission [see Fig. 4(a)]. For that a Golay cell detector has been placed behind the sample.

III. EXPERIMENTAL RESULTS

We begin with the transmissivity data obtained from the square-shaped sample. The data for $T = 40$ K are shown in Fig. 4(a) for different polarization states. Exciting the sample with right-handed circularly polarized radiation ($\sigma^+$) and sweeping the magnetic field, we observe two resonant dips at positive magnetic fields $B = 2.6$ and 3.35 T. Upon changing the radiation helicity from $\sigma^+$ to $\sigma^-$, the dips appear...
at negative magnetic fields. For linearly polarized radiation, the resonances are observed for both magnetic field directions (not shown). The resonances can be well fitted by a Lorentzian function. All these features are clear signs that the absorption of radiation is caused by cyclotron resonance of electrons. The dips in the transmissivity $T$ are detected in the temperature range from 4.2 up to 150 K. Below 4.2 K, the amplitude of both dips is smaller than the noise level of our setup. With rising temperature, the two dips increase in amplitude and merge together at $T$ above ~80 K [see inset of Fig. 4(a)]. The temperature dependence is due to the increasing carrier density with higher temperature and has been independently checked by magnetotransport data on the same sample [see Fig. 3(c)]. These results are in agreement with findings of Refs. [40,41] where double CR structures have been detected in similar systems by transmission and Faraday effect applying radiation of lower frequencies and attributed to top and bottom surface states.

From the cyclotron-resonance positions given by

$$B_{CR} = 2\pi f M_{CR} |e|, \quad (1)$$

where $e$ is the electron charge, we determined the correspondent cyclotron masses $m_{CR}$. At $T = 40$ K we obtained the masses $m_{CR} = 0.028 m_0$ and $0.035 m_0$, for dips at $B = 2.6$ and 3.35 T, respectively.

The masses agree well with the estimated cyclotron masses of surface states. We carried out $k \cdot p$ calculations of the band structure for the (013)-oriented 80-nm-wide HgTe film sandwiched between CdHgTe barriers adapting the procedure described in the Supplemental Material to Refs. [18] and [29,46]. We calculated the energy spectrum in zero magnetic field and then analyzed the Bohr-Sommerfeld/quasiclassical quantization in a magnetic field which allowed us to estimate the cyclotron mass. The details of our calculations for (013)-oriented structures taking into account built-in electric fields are given in the Appendix.

The obtained band structure and cyclotron masses as a function of the energy are shown in Fig. 5(a) and the inset, respectively. The calculations reveal the presence of surface states in the band gap of bulk strained HgTe. The Dirac points of the surface states for both top and bottom interfaces are deep in the valence band, which leads to level mixing and deviation of the energy dispersion from the linear one, similarly to the results obtained for (001)-oriented structures [18]. In (013)-grown structures, the energy spectrum is anisotropic in the interface plane. To illustrate the anisotropy, we plotted the band structure in Fig. 5(a) calculated for two perpendicular in-plane directions (solid and dashed lines). Moreover, compared to (001)-oriented films, we find that the spin carried by the surface electrons is tilted out of the interface plane, reflecting the low spatial symmetry of the (013)-oriented structure (see Appendix). Our calculation shows that the masses for surface states are very close to the experimentally detected ones and, also in agreement with experiment, vary only weakly with temperature [see Fig. 5(b)]. The detail comparison between the experimentally observed cyclotron masses and the calculated values require the knowledge of electric field distribution and chemical composition profile in real structures and is out of scope of this paper. We note that the density of bulk states in the valence band is very high due to large effective mass of holes. Therefore, the Fermi level in ungated samples and in gated samples at negative voltages is efficiently pinned to the valence band top. Thus, we conclude that the resonances are caused by the top/bottom surface states. This conclusion is also supported by magnetotransport data indicating a vanishing amount of bulk electrons. Moreover, according to the calculation, cyclotron resonance of the bulk carriers is expected at substantially higher magnetic fields corresponding to a mass of about 0.07$m_0$.

Next, we demonstrate that the CR, so far observed in transmission, results in a photocurrent, whose magnetic field and polarization dependencies fully reproduce the peak positions and shapes of the CR absorption. The magnetic field dependencies of the corresponding photosignals are shown for circularly or linearly polarized radiation in Figs. 4(b) and 4(c), respectively. The coincidence of the transmission and photocurrent resonance positions indicates that the current is also excited in the surface states. For a more detailed study of the photocurrent we used cross-shaped samples, which are too small to be used for transmission measurements, but allow fabrication of semitransparent gates.

Figure 6 shows the resonant photocurrent obtained for different radiation frequencies in an ungated cross-shaped sample. Comparison of the data for $f = 2.54$ THz obtained for square- and crossed-shaped samples shows that magnetic field positions of the resonances stay almost the same. Notice
that the relative strength of the first $B_{CR1}$ and second $B_{CR2}$ resonances substantially change with decreasing frequency. While at $f = 2.54$ THz the second resonance is substantially stronger than the first one, for $f = 0.69$ THz the situation reverses. The inset in Fig. 6 demonstrates that the position of both resonances linearly scales with the frequency. The frequency dependence of the CR is in line with transmissivity data of Ref. [39] of top and bottom surface states measured in similar strained HgTe film of 70 nm width.

In order to provide additional support for the conclusion that the observed resonant photocurrent and CR stem from two-dimensional surface states, we carried out measurements with the magnetic field tilted by an angle $\Theta$ (see Figs. 7(a) and 7(b)). Figure 7 shows that the current is caused by the magnetic field component $B_z$, normal to the surface. Indeed, calculating from the peak position $B_{CR}$ in Fig. 7, the value of $B_{CR}^z = B_{CR} \cos(\Theta)$, we obtain that $B_{CR}^z$ does not depend on the angle $\Theta$ (see inset). Moreover, for an in-plane magnetic field the photocurrent vanishes (not shown), indicating the two-dimensional nature of the carriers [47].

By using gated cross-shaped samples we study the photocurrent and CR as a function of the Fermi energy (see Figs. 8(a) and 8(b)). The data show that at negative-bias voltages, for which the Fermi energy lies in the valence band, the photocurrent resonances vanish. At positive gate voltages, the resonances in photocurrent at $B_{CR2} = 3.3$ T and $B_{CR1}$ at lower magnetic field are clearly resolved at both $T = 40$ and 20 K. The positions of the resonances are similar to those obtained for ungated samples (see Figs. 4 and 6), and

FIG. 6. (Color online) Normalized CR radiation-induced photocurrent measured for different radiation frequencies in ungated cross-shaped samples. Note that the data are $y$ shifted by 0.2 for $f = 1.62$ and 0.69 THz, respectively. Full lines show fits by the Lorentzian function. Inset shows the first $B_{CR1}$ (squares) and second $B_{CR2}$ (circles) resonance positions as a function of frequency. Full and open triangles show the data of Ref. [39] for top and bottom surface states measured in similar strained HgTe film of 70 nm width.

FIG. 7. (Color online) (a) Magnetic field dependencies of the photocurrent measured for magnetic field tilted by an angle $\Theta$ and linearly polarized light. The inset shows the resonance field $B_{CR}^z$ = $B_{CR} \cos(\Theta)$ as a function of angle $\Theta$.

FIG. 8. (Color online) (a), (b) Magnetic field dependence of the photocurrent measured for the gated cross sample #1 at different gate voltages $U_g$ at $T = 40$ and 20 K, respectively. Full lines show fits using a Lorentzian. Note that the data for various $U_g$ are $y$ shifted for clarity. In panel (b) the data for $U_g = 2$ and 3 V are multiplied by a factor 4. The inset in panel (b) shows $B_{CR1,2}$ determined from $J_x(B)$ for both temperatures. (c) Gate voltage dependencies of cyclotron masses obtained from the position of CR resonances $B_{CR1,2}$ determined from $J_y(B)$ and $J_x(B)$. (d) Magnetic field dependence of the photocurrent measured at low temperature and high magnetic fields.
This result agrees well with the above conclusion that the difference for negative and positive magnetic fields remains almost independent of the gate voltage, the corresponding cyclotron mass is \( m_{\text{CR}} = 0.07m_0 \). This mass matches the one calculated for bulk electrons, so that the resonance can be attributed to the CR of bulk electrons. We note that at \( T = 4.2 \, \text{K} \), the surface-state resonances are superimposed by Shubnikov–de Haas oscillations, which makes the CR analysis almost impossible.

From the resonance positions of the surface-state response, we determine the gate voltage dependence of the cyclotron masses [see Fig. 8(e)]. While the mass corresponding to \( B_{\text{CR2}} \) remains almost independent of the gate voltage, the \( B_{\text{CR1}} \) slightly rises with increasing \( U_g \). The resonance at \( B_0 \approx 3.3 \, \text{T} \) (\( m_{\text{CR}} \approx 0.036m_0 \)) is attributed to the bottom surface, whose electron density is not much influenced by the gate voltage. In fact, it is known from the magnetotransport measurements [see Fig. 3(f)] that the filling rates \( dN_s/dU_g \) for top and bottom surface states are considerably different because of electrostatic screening of the bottom surface by the top one. Moreover, the electron density at the top surface rises with the gate voltage increase [see Fig. 3(f)], which leads to the increase of the cyclotron mass. By contrast, the density of the bottom electrons is almost independent of the gate voltages [see Fig. 3(f)].

The theory which will be described following shows that the magnitude of surface photocurrents is determined by many parameters, including the carrier density and the asymmetry of electron scattering in momentum space, which all may depend on the gate voltage. Therefore, a connection between the photocurrent magnitude and the carrier density is intricate and the signal height does not allow drawing conclusions regarding the carrier density. For example, while at \( T = 40 \, \text{K} \), the photosignal \( U_\gamma \), calculated as one-half of the sum (dashed line) and the difference (solid line) for signals measured at negative and positive magnetic fields \( U'_\gamma = [U_\gamma(B > 0) + U_\gamma(B < 0)]/2 \).

Photocurrents are generated by two independent surface states (top and bottom). For the other direction, this situation just reverses: Now, the resonance at \( B_{\text{CR1}} \) is odd and \( B_{\text{CR2}} \) is even in magnetic field.

Our findings can be well understood in the framework of the asymmetric photoexcitation and/or energy relaxation of a nonequilibrium electron gas. The appearance of magnetic field induced photocurrents, excited by homogeneous radiation, is well known for two-dimensional systems lacking spatial inversion symmetry (for review, see Refs. [49,50]).

For free carrier absorption, being accompanied by electron scattering from phonons or static defects, the current is caused by the asymmetry of electron scattering in momentum space induced by an external magnetic field, when the electron systems are driven out of thermal equilibrium by light absorption. In the presence of a magnetic field, the rate of the scattering between the states with the momenta \( p \) and \( p' \) contains asymmetric \( B \)-field-dependent terms (odd in the electron wave vector) and can be presented in the form

\[
W_{pp} = W_{pp}^{(0)} + W_{pp}^{(1)} B, \tag{2}
\]

where \( W_{pp}^{(0)} \) is the scattering rate at zero field and \( W_{pp}^{(1)} \) is an asymmetric correction caused by the mixing of electron states by the magnetic field [51]. The terms in Eq. (2) satisfy \( W_{pp}^{(0)} = W_{-p-p}^{(0)} \) and \( W_{pp}^{(1)} = -W_{-p-p}^{(1)} \) due to time inversion symmetry.

The asymmetry of the carrier scattering in momentum space, which is caused by different scattering rates to the states with oppositely oriented momenta, leads to electric current generation. We note that at topological surface states, the electrons spin orientation is locked to its momentum [4,5]. This suggests that the observed photocurrents are spin polarized and accompanied by the emergence of a macroscopic surface spin polarization. As a specific feature of (013)-oriented surface, this spin polarization has a nonvanishing out-of-plane component (see Appendix). At cyclotron resonance, the 

![FIG. 9. (Color online) Magnetic field dependence of the photo- signal measured for two in-plane directions (x and y) obtained for gated cross sample #2 (\( U_g = 0 \)). The inset presents the normalized signal \( U'_\gamma \) calculated as one-half of the sum (dashed line) and the difference (solid line) for signals measured at negative and positive magnetic fields \( U'_\gamma = [U_\gamma(B > 0) + U_\gamma(B < 0)]/2 \).](image-url)

The asymmetry of the carrier scattering in momentum space, which is caused by different scattering rates to the states with oppositely oriented momenta, leads to electric current generation. We note that at topological surface states, the electrons spin orientation is locked to its momentum [4,5]. This suggests that the observed photocurrents are spin polarized and accompanied by the emergence of a macroscopic surface spin polarization. As a specific feature of (013)-oriented surface, this spin polarization has a nonvanishing out-of-plane component (see Appendix). At cyclotron resonance, the electron-photon interaction is enhanced, which results in a resonant behavior of the photocurrent.
Considering the generation of an asymmetric electron distribution in momentum space by cw radiation, the distribution evolution in the magnetic field and its decay due to scattering processes, one can write the Boltzmann equation for the distribution function $f_p$:

$$e[v \times B] \cdot \frac{\partial f_p}{\partial p} = g_p - \frac{f_p - \langle f_p \rangle}{\tau},$$  \hspace{1cm} (3)

where $p$ and $v$ are the electron momentum and velocity, respectively, $g_p$ is the generation rate of electrons in the state with the momentum $p$, $\tau$ is the momentum relaxation time, and $\langle f_p \rangle$ is the distribution function averaged over the momentum direction. Multiplying Eq. (3) by $e v$ and summing up over $p$ we obtain the equation for the photocurrent density $j = \sum_p e v f_p$ in the absence of an in-plane bias

$$-j \times \omega_c = G - \frac{j}{\tau},$$  \hspace{1cm} (4)

where $\omega_c = \omega C \cdot \hat{z}$, $\omega_c = e B_z/m_{CR}$ is the cyclotron frequency, $\hat{z}$ is the unit vector pointing along the $z$ axis, and $G = \sum_p e v g_p$ is the rate of current generation.

The direction and magnitude of the vector $G$ is determined by the asymmetry of scattering of surface carriers by static defects or phonons [see Eq. (2)] and the radiation absorption. In particular, the allowed asymmetric terms in Eq. (2) are determined by the spatial symmetry of the structure. For two-dimensional systems on (013)-oriented surfaces, the scattering rate acquires asymmetric terms even for the magnetic field perpendicular to the surface. This is due to the absence of any nontrivial symmetry elements in the C1 point group describing such structures. Moreover, in this system, the scattering asymmetry in the surface plane is not forced by symmetry to certain crystallographic axes. Therefore, the photocurrent generation rate $G$ in the out-of-plane magnetic field $B_z$ can be generally presented in the form

$$G = \gamma I \eta(\omega) B_z,$$  \hspace{1cm} (5)

where $I$ is the radiation intensity, $\eta(\omega)$ is absorbance, and $\gamma$ is the vector determined by the magnetic field induced asymmetry of electron scattering processes. As the direction of the vector $\gamma$ for the C1 point group is not forced to a certain crystallographic axis by symmetry arguments, it may depend on temperature, gate voltage, radiation frequency, etc. Note that such a specific anisotropy of (013)-oriented structures has been demonstrated for photogalvanic currents excited by terahertz radiation in HgTe quantum wells at zero magnetic field [52]. For two perpendicular in-plane directions, the solution of Eq. (4) has the form

$$j_x = \frac{\gamma_x + \omega_c \tau \gamma_y}{1 + (\omega_c \tau)^2} I \eta(\omega) B_z,$$

$$j_y = \frac{\gamma_y - \omega_c \tau \gamma_x}{1 + (\omega_c \tau)^2} I \eta(\omega) B_z.$$  \hspace{1cm} (6)

Equations (6) show that the current (i) has a resonant behavior at $\omega = \omega_c$ caused by CR in the absorbance $\eta(\omega)$ and (ii) contains contributions even and odd in the magnetic field, both in agreement with experiment. The formation of photocurrent for positive and negative magnetic fields $B_z$ is illustrated in Fig. 10, which sketches the generation rate vector $G$ for positive magnetic fields. The resulting photocurrent $j$ deviates from $G$ due to the Hall effect. For opposite magnetic field, the vector $G$ and the Hall rotation axis reverse as shown in Fig. 10(b). Consequently, the projections of the total photocurrent $j$ onto $x$ and $y$ direction, $j_x$ and $j_y$, may be odd or even in magnetic field $B$ as detected in experiment (see Fig. 9) and depicted in Fig. 10, but may also have the same parity [48]. In fact, the parity of the signal primarily depends on the photocurrent direction relative to the orientation of the contacts and the magnetic field strength determining the Lorentz force acting on moving carriers. Due to the fact that, as addressed above, the direction of the vector $G$ is arbitrarily oriented for the C1 point group, the parity of the signal may change with temperature, gate voltage, radiation frequency, etc.

IV. SUMMARY

To summarize, our results demonstrate that excitation of 80-nm-thick strained HgTe films by terahertz radiation results in cyclotron-resonance-induced photocurrents generated in the topologically protected surface states. The emergence of photocurrents reveals the importance of the magnetic field induced asymmetric scattering of nonequilibrium surface electrons. Due to the spin-momentum locking of surface electrons, the current is expected to be spin polarized; then, terahertz excitation results in a macroscopic surface spin polarization. As a specific feature of the (013)-oriented surface, this spin polarization has a nonvanishing out-of-plane component which can be probed by time-resolved Kerr rotation measurements. Our study demonstrates that the observed CR-assisted photocurrent can be applied even for micrometer-size samples, e.g., gated structures, and for Fermi level lying in the conduction band, i.e., under conditions where transmission can hardly be measured.

**APPENDIX**

We calculate electron spectrum in low-symmetry strained CdHgTe/HgTe/CdHgTe structure on CdTe in the framework of six-band $k \cdot p$ model which is relevant for narrow-gap semiconductors. We consider the class of $(0l\hbar)$-oriented films ($l$ and $\hbar$ are integer numbers) which includes $(011)$-, $(012)$-, and $(013)$-oriented structures. In the basis of Bloch amplitudes $\psi_{\Gamma_6}$ and $\psi_{\Gamma_8}$ bands, the wave function has the form

$$\Psi(\rho, z) = \begin{pmatrix} \psi_{\Gamma_6+1/2} \\ \psi_{\Gamma_6-1/2} \\ \psi_{\Gamma_8+3/2} \\ \psi_{\Gamma_8-3/2} \end{pmatrix} \exp(ik \cdot \rho),$$

where $\rho = (x, y)$ is the in-plane coordinate, $z$ is the growth axis, $\psi_j$ are the envelopes, $k_j = (k_x, k_y)$ is the in-plane wave vector.

The effective six-band Hamiltonian is given by

$$H = \begin{pmatrix} H_{cc} & H_{cv} \\ H_{cv}^\dagger & H_{vv} \end{pmatrix},$$

where the blocks $H_{cc}$ and $H_{cv}$ describe the conduction ($\Gamma_6$) and valence ($\Gamma_8$) intraband contributions, and the block $H_{cv}$ describes the band mixing. The block $H_{cv}$ is given by

$$H_{cv} = \begin{pmatrix} \frac{\hbar^2}{2m_0} \left( k^2 F(z) + 1 \right) k_x & \Xi_x \text{Tr} e \\ \Xi_y \text{Tr} e & 0 \end{pmatrix},$$

where $F(z)$ is the conduction band profile, $k = (k_x, k_y, -i/\hbar \partial_z)$, $F(z)$ is a parameter accounting for contribution from remote bands, $\Xi_x$ is the $\Gamma_8$-band deformation potential constant, and $e$ is the train tensor. The block $H_{vv}$ has the form

$$H_{vv} = \begin{pmatrix} \sqrt{k_z} P k_z & 0 & 0 \\ 0 & \sqrt{k_z} P k_z & 0 \\ 0 & 0 & \sqrt{k_z} P k_z \end{pmatrix},$$

where $P$ is the Kane matrix element and $k_{\pm} = k_z \pm ik_y$.

The block $H_{cv}$ is given by

$$H_{cv} = E_v(r) + H_{L}^{(a)} + H_{L}^{(b)} + H_{BP}^{(a)} + H_{BP}^{(b)},$$

where $E_v(r)$ is the valence band profile, $H_{L}^{(a)}$, $H_{L}^{(b)}$, $H_{BP}^{(a)}$, and $H_{BP}^{(b)}$ are the isotropic and anisotropic parts of the Luttinger and Bir-Pikus Hamiltonians.

$$H_{BP}^{(a)} = \frac{\hbar^2}{2m_0} \left[ -k \left( \gamma_1 + \frac{5}{2} \gamma_2 \right) k + 2(J \cdot k) \gamma_2 (J \cdot k) \right],$$

$$H_{BP}^{(b)} = \left( a + \frac{5}{4} b \right) \text{Tr} - b \sum_a \sum_{a \neq b} J^2_{a\alpha} \epsilon_{\alpha\beta} - b \sum_{a \neq b} J_a J_b \epsilon_{\alpha\beta},$$

where $\gamma_1$, $\gamma_2$, and $\gamma_3$ are contributions to the Luttinger parameters from remote bands, $J$ is the vector composed of the matrices of the angular momentum $\gamma_1$, $J_a = J_x^a + J_y^a + J_z^a$, $a$, $b$, and $d$ are the $\Gamma_8$-band deformation potential constants. The explicit form of the terms $H_{BP}^{(a)}$ and $H_{BP}^{(b)}$ related to the cubic anisotropy of host crystals depends on the coordinate frame used.

In the coordinate frame relevant to $(0l\hbar)$-oriented structures $x [100], y [0\hbar \tilde{h}]$, and $z [0l\hbar]$, the terms $H_{BP}^{(a)}$ and $H_{BP}^{(b)}$ assume the form

$$H_{BP}^{(a)} = \frac{2\hbar^2}{m_0} \left\{ \frac{\gamma_1 - \gamma_2}{2} k_x k_y, \frac{\gamma_1 + \gamma_2}{2} k_z \right\} + \left\{ \frac{\gamma_1 - \gamma_2}{2} k_x k_y, \frac{\gamma_1 + \gamma_2}{2} k_z \right\} \times \left[ \frac{(\gamma_1 - \gamma_2) k_z}{2} \cos \theta - \frac{J^2 - J^2_x}{2} \sin \theta \right],$$

$$H_{BP}^{(b)} = -2 \left( \frac{d}{\sqrt{3}} - b \right) \left\{ \frac{\gamma_1 - \gamma_2}{2} k_x k_y, \frac{\gamma_1 + \gamma_2}{2} k_z \right\} \times \left[ \frac{\gamma_1 - \gamma_2}{2} k_z \cos \theta + \frac{\epsilon_{zy} - \epsilon_{zy}}{2} \sin \theta \right],$$

where $\theta = \arctan(l/\hbar)$ is angle between the growth direction $[0l\hbar]$ and the [001] axis, $\theta \approx 18.4^\circ$ for $(013)$-oriented structures.

HgTe and Cd$_{0.65}$Hg$_{0.35}$Te layers adopt the in-plane lattice structure of CdTe buffer which leads to the in-plane strain of the lattice described by the strain tensor components $\epsilon_{xx} = \epsilon_{yy} = a_{\text{CdTe}} / a_0 - 1$, where $a_{\text{CdTe}}$ is the lattice constant of CdTe and $a_0$ is the equilibrium lattice constant of the considered layer. Out-of-plane components of the strain tensor in each layer can be found by minimizing the elastic energy. Such calculations for $(0l\hbar)$-oriented structures yield

$$\epsilon_{zz} = \frac{c_{11}^2 + c_{12}^2 (c_{11} - c_{44}) + c_{12} (3c_{11} - 2c_{44}) - (c_{11} + 3c_{12} - 2c_{44}) \cos 4\theta}{c_{11}^2 - 6c_{12} c_{44} + c_{12} c_{12} (c_{11} - c_{44}) \cos 4\theta},$$

$$\epsilon_{xy} = \frac{c_{11}^2 + c_{12}^2 (c_{11} - c_{44}) - (c_{11} + 3c_{12} - 2c_{44}) \cos 4\theta}{c_{11}^2 - 6c_{12} c_{44} + c_{12} c_{12} (c_{11} - c_{44}) \cos 4\theta},$$

where $c_{11}, c_{12}, c_{44}$ are elastic constants.

We have performed calculation of the electron spectrum and wave functions for the parameters listed in Table I.

The Schrödinger equation with the matrix Hamiltonian (A2) is solved numerically by expanding the envelope functions $\psi_j(z)$ in series of the harmonic oscillator functions.
following the procedure described for (001)-oriented structures in Ref. [46].

The calculated spectrum for the (013)-oriented structure is shown in Fig. 5. The wave functions of states emerging in the band gap of bulk strained HgTe are shown in Fig. 11. The states are localized at the film interfaces and predominantly formed from the heavy-hole states. Despite the fact that six-band $k \cdot p$ model used in the calculations neglects bulk inversion asymmetry of HgTe and the corresponding Dresselhaus spin-orbit interaction, we have found that the spin carried by surface states with $(013)$-oriented structures for $k_z \neq 0$ has an out-of-plane component. The out-of-plane polarization defined by

$$P_z = \frac{\int (|\psi_{\Gamma x,3/2}^+|^2 - |\psi_{\Gamma x,-3/2}^-|^2) \, dz}{\int (|\psi_{\Gamma x,3/2}^+|^2 + |\psi_{\Gamma x,-3/2}^-|^2) \, dz} \quad (A10)$$

is about 0.1 for the surface states presented in Fig. 11.

The emergence of the out-of-plane spin component is attributed to the cubic anisotropy incorporated in the Hamiltonian (A2) together with inversion symmetry breaking at surfaces. Indeed, the six-band $k \cdot p$ Hamiltonian of bulk crystal corresponds to the $O_h$ point group containing the spatial inversion. At a surface, the symmetry $z \leftrightarrow -z$ is broken which leads, for (013)-oriented surface, to the reduction of system symmetry to the $C_3$ point group containing the only nontrivial element $x \leftrightarrow -x$. Such a symmetry reduction enables the emergence of out-of-plane spin polarization for surface states with $k_z \neq 0$. We note that Dresselhaus spin-orbit interaction steaming from bulk inversion asymmetry of the host zinc-blende structure, which in not included in the model Hamiltonian, will lead to an out-of-plane spin polarization for surface states with $k_z \neq 0$.

PHYSICAL REVIEW B 92, 165314 (2015)

[47] Note that the corresponding magnetic length \( l_B = \sqrt{\hbar/(eB)} \) being about 16 nm for \( B \approx 3.3 \, \text{T} \) is smaller than the thickness of HgTe films (80 nm), so that for the bulk carriers one would expect CR even for in-plane magnetic fields.

[48] Note that the difference in parity of these two resonant photocurrents is not the rule. Both resonant photocurrents may have opposite parity but may also have the same parity as detected in experiments on another sample.
