Extraction of “RbSnBi” in liquid ammonia yielded the cluster anion \([\text{Sn}_2\text{Bi}_2]^{2-}\), which could be crystallized in the compound [Rb@2.2.2(crypt)][Sn4Bi4]·8.87 NH3. This anion is found to be derived from the formerly reported [Sn4Bi4]4- by the formal substitution of one tin atom by bismuth. In contrast, the extraction of “RbSn/Rb3Bi” in liquid ammonia yielded the anion \([\text{Sn}_3\text{Bi}_3]^{5-}\) in the compound Rb3[Sn3Bi3][Sn4]·6.75 NH3. The structural correlation of the two novel clusters indicates that \([\text{Sn}_3\text{Bi}_3]^{5-}\) might be an intermediate of the reaction pathway to \([\text{Sn}_2\text{Bi}_2]^{2-}\) and \([\text{Sn}_2\text{Bi}_2]^{3-}\). Each cluster is investigated by means of the electron localization function and further characterization was performed by using ESI-MS.

The field of homotopic polyanions of heavier main-group elements, the so-called Zintl anions, has been investigated since the beginning of modern chemistry. The insight into what kind of molecular structures may be built if only one element is employed forms part of our fundamental knowledge of main-group chemistry. Representative cluster anions that are present in a large number of the compounds known to date, and which can serve as building blocks for bigger clusters, are \([\text{Te}_3]^{4-}\) and \([\text{Te}_2]^{5-}\) (\(x = 3, 4\)) for group 14 elements (\(T = \text{Si}, \text{Ge}, \text{Sn}\)). \([\text{Zn}_3\text{Pn}_3]^{5-}\) (\(Pn = \text{P}, \text{As}\)) were obtained, in which the homoatomic \([\text{Pn}_3]^{5-}\) and \([\text{Te}_3]^{5-}\) structural motives are conserved.\(^{[3]}\)

Focusing on the tin bismuthides, this field is found to be scarcely investigated, as only three anions have been characterized to date, namely \([\text{Sn}_3\text{Bi}_3]^{5-}\), \([\text{Sn}_2\text{Bi}_2]^{3-}\), and \([\text{Sn}_2\text{Bi}_2]^{2-}\).\(^{[4-6]}\) The \([\text{Sn}_3\text{Bi}_3]^{5-}\) anion was initially synthesized by Corbett et al. in the compound [K@2.2.2(crypt)][Sn4Bi4]en in 1982, as one of the first heteroatomic Zintl anions.\(^{[7]}\) This compound was reproduced by Dehnen et al. and used as a starting material for reactions with transition metal and lanthanide metal complexes.\(^{[7]}\) In this manner, ternary anions like \([\text{Ni}_2\text{Sn}_2\text{Bi}_4]^{3-}\), \([\text{Ln}_2\text{Sn}_2\text{Bi}_4]^{3-}\), \([\text{Sn}_4\text{Bi}_4]^{2-}\) (\(L = \text{La}, \text{Ce}\)), and \([\text{Pd}_3\text{Sn}_6\text{Bi}_4]^{2-}\) were obtained. In the course of the reaction between [K@2.2.2(crypt)][Sn2Bi2]·en and ZnPh2, the binary anion \([\text{Sn}_2\text{Bi}_2]^{2-}\) crystallized together with \([\text{Zn}_3\text{Sn}_3\text{Bi}_6]^{2-}\). In 2012, we were able to add \([\text{Sn}_2\text{Bi}_2]^{2-}\) in the compound [Cs@18-crown-6]2[Sn4Bi4]·12NH3 as part of the very short list of known anions with the shape of a monocapped nortricyclane-like cage. Herein, we report the first synthesis of the similarly built anion \([\text{Sn}_3\text{Bi}_3]^{5-}\) in [Rb@2.2.2(crypt)][Sn4Bi4]·8.87 NH3 (1) and propose a possible correlation of both clusters with the, likewise, new \([\text{Sn}_3\text{Bi}_3]^{5-}\) anion, which we could crystallize from liquid ammonia in the compound Rb3[Sn3Bi3][Sn4]·6.75 NH3 (2).

Cluster compound 1 is obtained by the extraction of a solid-state starting material of the nominal composition “RbSnBi” with liquid ammonia in the presence of [2.2.2(crypt)]4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane. After approximately six weeks of storage at 236 K, black, block-shaped crystals form. A single-crystal X-ray structure determination revealed that compound 1 contains the novel anionic cluster \([\text{Sn}_3\text{Bi}_3]^{5-}\), which is disordered over two positions in the crystal structure, as shown in Figure 1 (top). Its structure compares to the previously reported \([\text{Sn}_3\text{Bi}_3]^{4-}\) anion if the apical position is exchanged by a bismuth atom. Thus, the \([\text{Sn}_3\text{Bi}_3]^{5-}\) anion consists of a formal nortricyclane-like \([\text{Sn}_3\text{Bi}_3]^{5-}\) cage with the two tin atoms in the basal plane and one additional Sn2+ cation capping the Sn1–Sn3–Bi4–Bi3 plane to form a tin triangle (Figure 1 bottom). The average atomic distances (\(d\) in \([\text{Sn}_3\text{Bi}_3]^{5-}\)) are \(d(\text{Sn}–\text{Sn}) = 3.1202(16)\) Å, \(d(\text{Sn}–\text{Bi}) = 2.9668(14)\) Å, and \(d(\text{Bi}–\text{Bi}) = 2.9724(7)\) Å. The height (\(h\)) of the cluster from the apical bismuth atom to the center of the basal plane is 4.1848(6) Å, whereas the shortest distance of the capping atom Sn2 to the Sn1–Sn3–Bi4–Bi3 plane is 1.8568(7) Å. The individual distances from Sn2 to Sn1/Sn3 and Bi3/Bi4 are 3.096 Å/3.120 Å and 2.998 Å/3.018 Å. All values match those found in the structurally related \([\text{Sn}_3\text{Bi}_3]^{4-}\) anion, in which only the apical bismuth atom Bi5 is substituted by a tin atom.
The electron localization function (ELF) for different orientations of the [Sn3Bi5]3– anion is shown in Figure 2 for isosurface value \( \eta = 0.63 \). Besides the core and monosynaptic basins, disynaptic basins can be found. The monosynaptic basins representing lone pairs are populated with 2.18–2.28 e– at the tin atoms and 2.28–2.55 e– at Bi2 and Bi5. A significantly higher population is found for Bi1, Bi3, and Bi4 with 2.75–2.99 e–. The higher population for monosynaptic bismuth basins is attributed to the higher electronegativity in contrast to the tin atoms. The difference among the bismuth atoms originates from the number of less electronegative tin atoms neighboring the particular bismuth atoms. Disynaptic basins, which represent two-center bonds, are found for all Sn–Bi and Bi–Bi bonds. The attractors of these basins are generally found a little way from the bonding axis of the atoms, indicating some cluster tension. The integral over the electron density of the disynaptic basins provides populations between 1.47 and 1.68 e–. The attractor of the trisynaptic basin is located inside the Sn1–Sn2–Sn3 triangle and is populated with 1.57 e–. The presence of the three-center bond explains the elongated homoatomic tin distances of about 3.1202(16) Å found by single-crystal X-ray diffraction.

For the preparation of compound 2, an equimolar mixture of the solid-state phases “RbSn2” and “Rb3Bi2” is extracted with liquid ammonia in the presence of [2.2.2]crypt. Within 8 weeks at 236 K, 2 crystallizes in the form of black hexagonal rods from the reddish brown reaction mixture. Single-crystal X-ray diffraction provided evidence for the formation of another unprecedented anion, [Sn3Bi3]5–. This anion consists of a tin triangle with one bismuth atom bridging every edge (Figure 3). The anion shows \( \text{C}_3 \) symmetry in the crystal structure; neglecting distortions caused by packing effects, it can be described in \( \text{C}_{\text{3v}} \) symmetry. The Sn–Sn atomic distance is 3.1244(16) Å and Sn–Bi bonds are 2.9807(12) Å and 2.9975(11) Å. The shortest distance between two bismuth atoms is 4.897(12) Å \( \left( r_{\text{vdW}}(\text{Bi}) = 1.535 \text{ Å} \right) \). The opening angle, \( \alpha \), between the tin triangle and each of the other triangles is 138.95(3)°. In the crystal structure, the anion is surrounded by rubidium cations, forming a framework with channel-like cavities. These channels are filled with [Sn4]4– tetrahedra, rubidium cations, and ammonia molecules, all showing disorder. Three of the five negative charges of the anion can formally be assigned to the two bonded bismuth atoms. The remaining two charges are to be shared equally between the three tin atoms. Furthermore, the [Sn3Bi3]5– anion can be described by Wade–Mingos rules. It has \( (3 \times 4 + 3 \times 5 + 5) = 32 \) valence electrons and \( (32 – 6 \times 2)/2 = 10 \) skeletal electron pairs. Taking into account the six vertices, the anion is a hypho cluster \((n + 4)\). The formal derivation of the [Sn3Bi3]5– anion from the corresponding nine-atom closo-type cluster is shown in Figure 4.

The electronic situation is illustrated by the ELF, which is shown in Figure 5 for different orientations of the anion at \( \eta = 0.63 \). Each bismuth atom has two monosynaptic basins with populations of 2.44–2.52 e–. Each tin atom has one monosynaptic basin populated with 2.17–2.23 e–. The higher population of the monosynaptic bismuth basins is again rationalized.
by the higher electronegativity of the bismuth atoms. An attractor for a disynaptic basin can be found close to every Sn/C0 Bi bond. The integral over the electron density has the average value of 1.40 e/C0, the trisynaptic basin inside the tin triangle is populated with 1.46 e/C0. Table 1 gives an overview of the basin populations, comparing anions \([\text{Sn}_3\text{Bi}_3]^{5-}\), \([\text{Sn}_3\text{Bi}_5]^{3-}\), and \([\text{Sn}_4\text{Bi}_4]^{4-}\). The overall population in all three anions is shifted from bonding basins to valence basins; a shift that is already known for such heavy polyanions and is slightly more pronounced for \([\text{Sn}_3\text{Bi}_3]^{5-}\). This might indicate that, through reorganization processes in solution, the system tends to form anions with a more electron precise situation. The populations of monosynaptic tin basin \(V(\text{Sn})\) stay almost constant for the different sized clusters, whereas the populations at the bismuth atoms \(V(\text{Bi})\) adapt to the varying bonding situations in the anions, as these are directly involved in the formation of new bonds.

As no covalent bonds are present between the bismuth atoms, it can be assumed that the stabilization of the \([\text{Sn}_3\text{Bi}_3]^{5-}\) ion in the observed geometry arises from the repulsion of the free electron pairs, and that the \([\text{Sn}_3\text{Bi}_3]^{5-}\) anion might be an intermediate of the reaction pathway to bigger clusters. The formation of \([\text{Sn}_3\text{Bi}_5]^{3-}\) and \([\text{Sn}_3\text{Bi}_5]^{3-}\) support this assumption, as these anions contain the \([\text{Sn}_3\text{Bi}_3]^{5-}\) fragment (Figure 6). Furthermore, the main characteristics of the geometry and the electronic structure of the \([\text{Sn}_3\text{Bi}_3]^{5-}\) cluster are present in both anions. Starting from the \([\text{Sn}_3\text{Bi}_3]^{5-}\) cluster, the addition of either a “Sn-Bi” or a “Bi-Bi” dumbbell completes the corresponding eight-atom clusters. Upon the formal introduction of the dumbbell, the angle between the basal plane and the tin triangle is opened slightly from 138.95(3)° in \([\text{Sn}_3\text{Bi}_3]^{5-}\) to 139.764(11)° in \([\text{Sn}_4\text{Bi}_4]^{4-}\) and 141.81(4)° in \([\text{Sn}_3\text{Bi}_5]^{3-}\). The angles between the tin triangle and the two remaining triangle planes are reduced by about 10° in both anions. Thus, the distances between atoms Bi3 and Bi4 are reduced to about 4.4 Å, as compared to 4.897(12) Å in \([\text{Sn}_3\text{Bi}_3]^{5-}\). The distances of Bi3/ Bi4 to Bi1 are about 4.6 Å for both eight-atom clusters. A similar transformation from \([\text{K}@[2.2.2]\text{crypt}]_2[\text{Sn}_2\text{Bi}_2]\cdot\text{en}\) to \([\text{K}@[2.2.2]\text{crypt}]_2[\text{Sn}_3\text{Bi}_3]\cdot\text{en-tol}\) was reported by Lips and Dehnen in 2009.

For ESI-MS characterization, both syntheses were performed in ethylenediamine/dimethylformamide. For “RbSnBi”, among others, the singly charged fragments \([\text{Sn}_3\text{Bi}_3]^{-}\), \([\text{Sn}_3\text{Bi}_5]^{-}\), and \([\text{Sn}_3\text{Bi}_5]^{-}\) could be detected, whereas the reaction mixture of “RbSnBi” decomposes so rapidly that only the \([\text{Sn}_3\text{Bi}_3]^{-}\)

Table 1. Population of bonding basins in the \([\text{Sn}_3\text{Bi}_3]^{5-}\), \([\text{Sn}_3\text{Bi}_5]^{3-}\), and \([\text{Sn}_4\text{Bi}_4]^{4-}\) anions.

Computational studies were performed by using the program DGRID was used.[10] ESI-MS characterization experiments were performed on a TQS 7000 spectrometer from Thermoquest Finnigan in the negative- tion pathway to clusters like $[\text{Sn}_3\text{Bi}_5]^{3+}$ structure. The anion is probably an intermediate of the reaction.

In summary, we were able to crystallize and structurally characterize the novel $[\text{Sn}_3\text{Bi}_5]^{3+}$ anion, which has a crown-like structure. The anion is probably an intermediate of the reaction pathway to clusters like $[\text{Sn}_3\text{Bi}_5]^{3+}$ and $[\text{Sn}_4\text{Bi}_4]^{4+}$. The main characteristics of the geometry and the electronic structure of the $[\text{Sn}_3\text{Bi}_5]^{3+}$ anion are maintained in the latter two anions. The $[\text{Sn}_3\text{Bi}_5]^{3+}$ anion was structurally characterized for the first time and can formally be derived from the $[\text{Sn}_3\text{Bi}_5]^{4+}$ anion by exchange of the apical tin atom by bismuth.

### Experimental Section

$\text{Rb}[[2.2.2]\text{crypt}]_2[\text{Sn}_3\text{Bi}_5][\text{NH}_3]$, (1): “$\text{RbSnBi}_2$” (165 mg, 0.2 mmol) and (2.2.2)crypt (113 mg, 0.3 mmol) were weighed into a baked-out Schlenk tube. Afterwards, dry ammonia (about 10 mL) was condensed, forming a red–brown solution. The Schlenk tube was stored at 236 K. 1 was obtained in about 10% crystalline yield. $\text{Rb}_2[\text{Sn}_3\text{Bi}_5][\text{NH}_3]$, 6.75 NH$_3$, (2): “$\text{RbSn}_3$” (323 mg, 1 mmol), “$\text{RbSn}_2$” (674 mg, 1 mmol), and (2.2.2)crypt (80 mg, 0.2 mmol) were weighed in a baked-out Schlenk tube and ammonia (about 10 mL) was condensed. The red-brown reaction solution was stored at 236 K. 2 was obtained in 10–20% crystalline yield.

Single-crystal X-ray diffraction data for both compounds were recorded on a SuperNova (Agilent technologies) at 123 K with Mo radiation ($\lambda_{\text{Mo}}$ = 0.71073 Å).[9] The crystals were selected under perfluoroalkylether and mounted on a loop (MiTeGen, 200 μm) in a stream of cool nitrogen.

The structures were solved with olex.solve and refined on $P^2_1$ by using SHELXL-L.[9] For illustrations, the program Diamond was used.[9] For its representations, the program COSMO model was applied with $\varepsilon$ = 16.9; all other default options of the program were accepted. For the calculations of the ELF, the program DGRID was used, and for its representations, the program OpenBabel was used.[31]

A Step in Between: \([\text{Sn}_3\text{Bi}_3]^{5-}\) and Its Structural Relationship to \([\text{Sn}_3\text{Bi}_5]^{3-}\) and \([\text{Sn}_4\text{Bi}_4]^{4+}\)

**Cage fight:** The new crown-like \([\text{Sn}_3\text{Bi}_3]^{5-}\) anion can be seen as the missing link between the also new \([\text{Sn}_3\text{Bi}_5]^{3-}\) anion and the previously reported \([\text{Sn}_4\text{Bi}_4]^{4+}\) anion. Both cages are formally derived by capping the crown with either a Bi–Bi or a Sn–Bi dumbbell. The main structural and electronic features of the fragment are conserved, especially the three-center bond of the Sn triangle.
